The Architectural Foundations of Navier–Stokes in Event Density

Form Derivation, Clay-Relevance Decomposition, and the Structural Status of Turbulence

Allen Proxmire

April 2026

Abstract

Classical fluid mechanics describes the Navier–Stokes equations as a phenomenological set of conservation laws without an architectural explanation of why the equations take their specific form, why 2D NS is globally smooth while 3D NS smoothness remains the open Clay problem, or why turbulence lacks a canonical structural template across systems. We present a unified architectural account of these questions within the Event Density (ED) program, integrating five closed structural arcs. **NS-1** establishes that ED's canonical PDE forces D = 3+1 via a Path B-strong argument combining architectural d 3 (T20 mechanism degeneracy at d 2), architectural-suggestive d 3 (Polya recurrence + concentration of measure + decoupling-surface degeneration), and empirical-consistency closure (T19/T20 outputs match observed gravity at d = 3). **NS-2** derives the standard Newtonian-fluid NS form from substrate primitives via two concordant routes — chain-substrate coarse-graining and partial vector-extension of the canonical PDE — with advection, pressure, and incompressibility catalogued as fluid-mechanical additions not native to ED canonical channels. **NS-3** reaches an Intermediate Path C verdict: ED contains a real Clay-NS-relevant regularizing mechanism (R1: form-FORCED $-\kappa\mu_{V1}\ell_P^2\nabla^4 v$ stabilization arising from V1's finite-width vacuum kernel), with quantitative competition against destabilizing super-Burnett terms INHERITED on both sides. **NS-Smoothness** formalizes the Clay-relevance decomposition: R1 produces strictly monotone gradient-norm Lyapunov decay in ED-only NS (without advection), while the advective vortex-stretching term $\int \omega \cdot S\omega \, dV$ is the unique indefinite-sign contribution to dL/dt in full 3D NS. **NS-Turb** closes the P7 turbulence-cascade mapping at H1 trivial / H2 partial / H3 fail — no architectural template for developed-cascade turbulence. Three independent program-level analyses converge on advection as structurally non-ED at architectural (NS-2.08), dynamical (NS-Smooth-3), and spectral (NS-Turb-4) levels. The synthesis yields a unified structural picture: ED supplies real architectural regularization and canonical NS form-derivation, but advection — the unique obstruction to ED-style smoothness — is structurally non-ED at three independent levels. Event Density explains why the NS form appears, why 2D NS is globally smooth (vortex-stretching vanishes identically), and why 3D NS smoothness is structurally hard (the obstruction lies outside the canonical regularizing architecture). It does not resolve whether 3D NS blows up at finite time, predict critical Reynolds numbers, or supply a turbulence-cascade architectural template. This paper provides the first unified architectural account of Navier–Stokes within the Event Density program, complementing the empirical P4-NN rheology paper that covers ED's reach into non-Newtonian fluid mechanics.

---

1. Introduction

1.1 Motivation

The Navier–Stokes equations are the empirically successful description of viscous incompressible fluid flow, validated across a vast range of laboratory and engineering regimes. Their phenomenological success contrasts sharply with the structural questions they leave open. Why does the velocity field obey precisely the equation it obeys, and not some other equation with similar dimensional content? Why does the same equation in two spatial dimensions admit global smooth solutions for arbitrary finite-energy data, while in three spatial dimensions the analogous question — the Clay Millennium smoothness problem — has remained open for nine decades? Why does turbulence, the developed nonlinear regime of 3D NS, lack a single canonical structural account that crosses systems and Reynolds numbers? Standard fluid mechanics treats these questions as either resolved by observation (the equation works), as deferred to mathematics (Clay-NS), or as phenomenological complexity (turbulence). What is missing is an architectural account of the equation itself.

This paper presents such an account within the Event Density (ED) program, an architectural framework whose canonical scalar partial differential equation derives from substrate-level commitments rather than fluid-mechanical postulates. The relationship between ED and Navier–Stokes turns out to be neither one of identity nor of irrelevance. ED reproduces the *viscous* content of NS at architectural level, derives the *dimensional structure* (D = 3+1) from substrate-level arguments, and supplies a *regularizing mechanism* that would close the Clay smoothness question were it not for a structural feature ED does not natively absorb — the advective convective derivative.

1.2 Event Density as an architectural framework

Event Density is a relational substrate ontology. Its primitives include discrete micro-events, channels along which micro-events propagate, chains as worldline-class persistent structures, decoupling surfaces as participation thresholds, and primitive-level commitment irreversibility. From these substrate primitives plus seven structural canon principles (P1–P7), ED derives a canonical scalar nonlinear PDE that has been shown to generate, in three nominally separate domains, the foundational structures of physics: the four postulates of non-relativistic quantum mechanics, the substrate-derived form of Newton's gravitational law together with the MOND transition acceleration and the slope-4 baryonic Tully–Fisher relation, and a universal degenerate-mobility law that fits soft-matter diffusion data across ten chemically unrelated systems with $R^2 > 0.986$ at common exponent $\beta = 1.72 \pm 0.37$.

The ED program is summarized in [*Event Density: One Substrate, Three Domains*] (Proxmire 2026); the present paper extends the program's structural reach into mainstream classical fluid mechanics, focused specifically on the Navier–Stokes equations and the Clay smoothness problem.

1.3 The five closed Navier–Stokes arcs

The structural content of this paper integrates five closed program arcs:

- **NS-1** (Path B-strong dimensional forcing): ED's canonical PDE forces D = 3+1 via three concordant lines.
- **NS-2** (substrate derivation of NS form): standard Newtonian-fluid NS form derivable via two distinct substrate routes.
- **NS-3** (Intermediate Path C): ED contains a real Clay-NS-relevant regularizing mechanism with quantitative competition INHERITED.

- **NS-Smoothness** (Clay-relevance decomposition): formal R1 + advection-obstruction decomposition.
- **NS-Turb** (turbulence cascade): no architectural template for developed-cascade turbulence.

Each arc is structurally complete; this paper consolidates and integrates them.

1.4 Scope

The paper presents the architectural-decompositional content of ED's relationship to Navier–Stokes. It does not solve the Clay-NS smoothness problem, predict critical Reynolds numbers for any specific transition, supply turbulence closure models (LES, RANS, sub-grid), or propose architectural extensions to absorb advection canonically. It catalogues what is delivered by the existing canon and what lies beyond.

The empirical content of ED's reach into non-Newtonian fluid mechanics (jamming, discontinuous shear-thickening, Cross/Carreau shear-thinning, Maxwell-class viscoelasticity) is the subject of a companion paper, *ED Mobility Saturation Predicts Non-Newtonian Rheology* (the P4-NN paper). The two papers together cover the program's published-grade content on classical fluids.

1.5 Contributions

- A unified architectural account of why the Navier–Stokes form appears, derived from substrate primitives via two concordant routes.
- A formal Clay-relevance decomposition: ED's R1 mechanism (positive side) + advective vortex-stretching (negative side, structurally non-ED).
- A three-angle convergence theorem: advection is identified as structurally non-ED at architectural, dynamical, and spectral levels independently.
- A structural account of the 2D-versus-3D smoothness asymmetry: vortex-stretching, the obstruction to ED-style monotone gradient-norm decay, vanishes identically in 2D and is sign-indefinite in 3D.
- An honest catalogue of what ED explains (form derivation, dimensional forcing, structural decomposition of Clay difficulty) and what it does not (Clay-NS resolution, Reynolds-number predictions, turbulence-cascade template).

1.6 Paper organization

Section 2 lays out the ED architectural background. Section 3 derives the Navier–Stokes form from ED via the two concordant substrate routes. Section 4 introduces the R1 regularizing mechanism. Section 5 analyzes the advection obstruction. Section 6 establishes the three-angle convergence on advection-as-non-ED. Section 7 presents the Intermediate Path C Clay-relevance verdict. Section 8 closes the turbulence question. Section 9 synthesizes the unified picture. Section 10 concludes. Appendices A–C provide key equations, closed-arc summaries, and architectural canon references.

---

2. Architectural Background

2.1 The ED canonical PDE

The canonical Event Density partial differential equation, established in the program's foundational papers, takes the form

$$\partial_t \rho \;=\; D \cdot F[\rho] \;+\; H \cdot v, \qquad D + H = 1, \qquad D, H \in [0,1],$$

$$\dot{v} \;=\; \tau^{-1}(\bar{F}(\rho) - \zeta\, v),$$

with the operator

$$F[\rho] \;=\; M(\rho)\,\nabla^2 \rho \;+\; M'(\rho)\,|\nabla \rho|^2 \;-\; P(\rho).$$

Three constitutive channels — mobility (M), penalty (P), and global participation (v) — are jointly necessary and sufficient to satisfy seven structural principles P1–P7 that define the ED equivalence class. The canonical scalar PDE acts on a bounded density field $\rho(\mathbf{x}, t)$. A vector-extension framework, articulated in Architectural_Canon_Vector_Extension, lifts the architectural principles to vector and tensor field structures while preserving the architectural canon's content.

2.2 P1–P7: the Architectural Canon

The seven canon principles are stated in compressed form below. Detailed treatments are in the foundational ED literature.

- **P1 — Operator structure.** $F[\rho] = M(\rho)\nabla^2\rho + M'(\rho)|\nabla\rho|^2 - P(\rho)$ is the unique three-term form satisfying locality, isotropy, and the dissipative-structure constraints.
- **P2 — Channel complementarity.** $\partial_t \rho = D \cdot F[\rho] + H \cdot v$ with $D + H = 1$, splitting dynamics into direct (substrate operator) and mediated (participation feedback) channels.
- **P3 — Penalty equilibrium.** The penalty function $P(\rho)$ has a unique zero at $\rho = \rho^*$, with $P'(\rho^*) > 0$, ensuring monostable equilibrium structure.
- **P4 — Mobility capacity bound.** The mobility function $M(\rho)$ satisfies $M(\rho_{\max}) = 0$ with $M(\rho) > 0$ for $\rho < \rho_{\max}$, encoding finite packing capacity.
- **P5 — Participation feedback.** The global participation variable $v(t)$ obeys $\dot{v} = \tau^{-1}(\bar{F}(\rho) - \zeta v)$, supplying memory and oscillatory structure.
- **P6 — Damping discriminant.** A canonical damping discriminant determines underdamped versus overdamped regimes at $D_{\text{crit}} \approx 0.896$ (canonical $\zeta = 1/4$).
- **P7 — Nonlinear triad coupling.** The nonlinearity $M'(\rho)|\nabla\rho|^2$ generates harmonic content at the few-percent level (canonical 3–6% at $k = 3$ from $k = 1$ driving) under multiplicative perturbations.

2.3 Vector extension

The canonical PDE acts on a scalar density. The Architectural Canon Vector Extension establishes that P1–P7 are field-type-agnostic at the architectural level: vector and tensor field PDEs satisfying P1–P7 component-wise are architecturally ED, even when they violate the concrete-PDE-level constraint C5 (single scalar field) of the canonical exemplar. A three-tier classification distinguishes: canonical (scalar, satisfying both C-level and P-level constraints), fully ED-architectural (vector/tensor, satisfying P-level), and partially ED-architectural (containing P-level content plus structural additions not native to the canon).

This framework will be load-bearing in Section 3, where we treat the Navier–Stokes velocity field as a candidate for partial-ED-architectural status.

2.4 Form-FORCED versus value-INHERITED methodology

A persistent distinction throughout the ED program separates:

- **Form-FORCED** content — functional forms derivable from architectural principles and admitting no alternative within the canon.
- **Value-INHERITED** content — specific numerical parameters that the canon does not determine and that are inherited from material-specific physics or experimental input.

This distinction is methodological: the ED program does not claim to predict every numerical value in physics from primitives alone. It claims that the *forms* of physical laws — the functional structures of equations and the qualitative existence of phenomena — follow as theorems from substrate commitments. Specific values fall under empirical or material-specific physics. The Navier–Stokes program preserves this discipline throughout.

---

3. Deriving Navier–Stokes from Event Density

3.1 Path B-strong: D = 3+1 forced

The first structural question for any architectural derivation of Navier–Stokes is dimensional: why three spatial dimensions plus one time dimension? Standard fluid mechanics takes D = 3+1 as observational input. NS-1 closes this question via a Path B-strong argument that combines three concordant lines:

Architectural lower bound ($d \geq 3$). The substrate-gravity arc's transition-acceleration mechanism (T20) requires the cosmic decoupling surface to project anisotropically onto an accelerating chain via the dipole spherical harmonic ($\ell = 1, m = 0$). This projection geometry degenerates at $d \leq 2$: the cosmic horizon's S^{d-1} has no separate polar-azimuthal decomposition for $d - 1 \leq 1$, and the canonical 2 azimuthal periodicity that yields $a_0 = c \cdot H_0/(2\pi)$ has no analog. ED cannot host its own substrate-gravity arc at $d \leq 2$ — an internal-consistency forcing of $d \geq 3$.

Architectural-suggestive upper bound ($d \leq 3$). Three independent primitive-anchored mechanisms converge: (i) concentration of measure on participation neighborhoods (in high d, near/far discrimination collapses); (ii) Polya recurrence/transience boundary (random walks on $\mathbb{Z}^d$ are recurrent for $d \leq 2$, transient for $d \geq 3$, with the $d = 3$ marginal regime supporting cross-chain participation overlap that V1 sourcing requires); (iii) ED-06 decoupling-surface boundary/bulk degeneration in high-dimensional balls. Polya is the load-bearing mechanism; concentration and decoupling-degeneration are concordant supporting arguments. Each carries an identification gap (chain-dynamics-as-diffusion at coarse-grained scale; participation-bandwidth as probability measure; ED-06 ontology as Euclidean-ball geometry). The combined argument does not rise to a strict-architectural theorem but is structurally suggestive.

Empirical-consistency closure ($d \leq 3$). T19's holographic-bound derivation and T20's dipole-mode mechanism produce, in arbitrary d-spatial, gravity laws of form $a \propto M/r^{d-1}$ and prefactor structures dependent on S^{d-1} harmonic decomposition. Empirical Newton ($1/\mathrm{r}^2$) and empirical a_0 ($\sim 1.2 \times 10^{-10}\,\mathrm{m/s^2}$) match the substrate-gravity outputs only at $d = 3$. The substrate primitives are d-agnostic at primitive-statement level; the d = 3 specification enters via empirical match to observed gravity.

The aggregate verdict (Path B-strong) closes B2 at multi-layer architectural plus empirical-consistency level. D = 3+1 is forced by ED's structural framework when taken in conjunction with observed gravity. The forcing is multi-source, layer-attributed, and structurally honest:

the seven PDE-uniqueness axioms alone do not force D = 3+1, but ED's full primitive-plus-substrate-plus-empirical framework does.

3.2 Substrate-level derivation of the NS form

NS-2 derives the standard Newtonian-fluid Navier–Stokes form from substrate primitives via two methodologically distinct but structurally concordant routes.

Chain-substrate route (NS-2.01–NS-2.07). A coarse-graining cell of radius R_{cg} is defined, satisfying three constraints simultaneously: chain-discreteness suppression (R_{cg} much larger than substrate UV cutoff ℓ_P), hydrodynamic regime (R_{cg} much larger than mean free path λ_{mfp}), and field-structure preservation (R_{cg} much smaller than flow scale L_{flow}). Within this scaling window, four substrate conserved quantities are identified — chain count, chain mass (from Arc M), chain momentum, and chain bandwidth content (energy-class) — and their fluxes through the coarse-graining cell boundary are computed via 2-sphere boundary integration parallel to T19's holographic-bound mechanism. The resulting flux forms

$$\mathbf{J}_\rho = \rho\mathbf{v}, \qquad \Pi_{ij} = \rho v_i v_j + \tau_{ij}, \qquad \mathbf{J}_e = e\mathbf{v} + \mathbf{v}\cdot\tau + \mathbf{Q}$$

feed directly into the continuity, momentum-balance, and energy equations. The stress tensor τ_{ij} decomposes into pressure plus Newtonian viscous deviatoric plus an ED-specific residual that is structurally identified at substrate level but numerically negligible at NS scales. The result is the standard Newtonian-fluid Navier–Stokes form.

ED-PDE-direct route (NS-2.08). Independently, the canonical scalar PDE's three channels are mapped onto velocity-field components via the partial vector-extension framework. The mobility/gradient channel applied component-wise to velocity components yields the viscous term $\mu\nabla^2 v_i$, with the canonical $D{\cdot}M$ identified as the kinematic viscosity ν. The compositional rule's gradient-penalty content corresponds to the same viscous structure viewed at the configuration-space layer.

Both routes produce the same Newtonian-fluid form. The chain-substrate route explains coefficient origin (viscosity emerges from kinetic + cross-chain V5 + V1-mediated contributions, with values inherited at substrate level); the ED-PDE-direct route explains architectural form (viscous content is canonical ED architecture; pressure / advection / incompressibility are flagged as fluid-mechanical-additions).

3.3 Partial vector extension and the NS form

The vector-extension framework permits NS to be classified within the three-tier scheme of Section 2.3. NS satisfies the architectural canon's content for its viscous component: the mobility channel applied component-wise to velocity gives Newtonian viscous diffusion as a clean P1-class content, and the principles P2–P7 generalize component-wise without violation. NS does not satisfy the canon's content for its pressure, advective, and incompressibility content: these are structural features of fluid kinematics that lie outside the canonical P1–P7 framework.

NS is therefore **partially ED-architectural** in the three-tier classification: its viscous content is canonical ED vector-extended; its pressure, advection, and incompressibility content is fluid-mechanical-specific structural addition that the canon does not natively absorb.

3.4 Identification of advection, pressure, and incompressibility as fluid-mechanical additions

The catalogue of fluid-mechanical additions, established in NS-2.08, comprises three structural features:

- **Pressure as Lagrange multiplier.** In incompressible NS, pressure is a Lagrange multiplier enforcing $\nabla \cdot \mathbf{v} = 0$. It is not derived from any ED canonical channel; it is a fluid-mechanical structural device required for coherence with the holonomic constraint of incompressibility.
- **Advective convective derivative.** The term $(\mathbf{v} \cdot \nabla)\mathbf{v}$ is a kinematic coupling between velocity components arising from the fact that velocity both *is* the advecting flow and *is being* advected. It has no analog in any P-level canonical channel: it is symmetric in neither index pattern nor scaling structure with any P1-class operator content.
- **Incompressibility constraint.** $\nabla \cdot \mathbf{v} = 0$ is a holonomic constraint not derivable from any P-level canonical principle. It enters as a fluid-mechanical commitment characterizing the regime (low-Mach-number limit of compressible NS) rather than as a substrate-derived structural fact.

These three additions are structurally significant for the rest of the paper: pressure and incompressibility, despite being fluid-mechanical-specific, contribute zero or vanish appropriately in the gradient-norm Lyapunov analyses of Sections 4 and 5; advection alone produces the Clay-NS-relevant obstruction.

3.5 Concordance of the two derivation routes

The two derivation routes — chain-substrate kinetic-theory-class coarse-graining and ED-PDE-direct vector-extension — produce the same Newtonian-fluid Navier–Stokes form. The concordance is non-trivial: the routes operate at different methodological layers (substrate-level statistical coarse-graining versus architectural-canon component-wise application) and use disjoint analytical machinery, yet converge on identical equations. This concordance constitutes structural evidence that ED's content for the viscous part of NS is not an artifact of any single derivation framework. The remaining structural additions (pressure, advection, incompressibility) appear identically in both routes as fluid-mechanical-specific content not derivable from substrate primitives or from canon principles.

---

4. The R1 Mechanism

4.1 Origin of R1 from V1's finite-width vacuum kernel

Theorem N1 of the Event Density program establishes the existence of a vacuum response kernel $K_{\text{vac}}(x, x')$ that is Lorentz-scalar, finite-width on the substrate scale ℓ_{ED}, and sub-power-law-2 decaying. Combined with the Newton-recovery argument in T19 (which forces $\ell_{\text{ED}} = \ell_P$, the Planck length), this kernel becomes the structural object on which the R1 mechanism is built.

When the substrate-level vacuum response kernel is coarse-grained to fluid-mechanical scales via multi-scale expansion in the small parameter $\varepsilon = \ell_P/L_{\text{flow}}$, the leading-order substrate-cutoff correction to the continuum Navier–Stokes momentum equation appears as a higher-derivative regularization term:

$$\rho \frac{Dv_i}{Dt} = -\partial_i p + \mu \nabla^2 v_i \; - \; \kappa \mu_{V1} \ell_P^2 \nabla^4 v_i + \rho f_i^{\text{ext}},$$

with coefficient κ form-FORCED positive by V1 being a positive smoothing kernel (its Fourier transform $\widehat{K}(k) = K_0[1-\alpha(k\ell_P)^2+\cdots]$ has $\alpha > 0$ for all positive monotonically-decreasing-in-$|k|$ kernels). The magnitude μ_{V1} is inherited via V1's specific G-function profile.

4.2 Form-FORCED $\nabla^4 v$ stabilization

The R1 term $-\kappa\mu_{V1}\ell_P^2\nabla^4 v_i$ is the structural shadow of ED's substrate UV cutoff in the continuum momentum equation. Three structural facts characterize it:

1. **Existence is form-FORCED.** The term arises from V1's finite-width substrate-level kernel under multi-scale expansion. It is not optional: any continuum NS theory respecting ED's canonical V1 kernel structure includes the term.
2. **Sign is form-FORCED positive.** The $\kappa > 0$ sign is forced by V1's positive-smoothing-kernel structure. The term is dissipative (energy-removing in the momentum equation; gradient-removing in the gradient-norm Lyapunov).
3. **Magnitude is value-INHERITED.** The coefficient $\kappa\mu_{V1}$ depends on V1's specific G-function profile, which is inherited from material-specific substrate physics rather than fixed by the canon at primitive level.

The term is suppressed by the ratio $\ell_P^2/L^2 \leq 10^{-60}$ at laboratory NS scales but activates at substrate-approaching gradient scales. This is the regime where the R1 mechanism becomes Clay-relevant: in any putative finite-time blow-up trajectory, gradients reach scales where R1 dominates the dissipative content of the equation.

4.3 Gradient-norm Lyapunov structure

Define the gradient-norm Lyapunov functional

$$L(t) = \frac{1}{2}\|\nabla \mathbf{v}(t)\|_2^2 = \frac{1}{2}\int_{\mathbb{R}^3} \partial_j v_i\, \partial_j v_i\, dV.$$

This is enstrophy-class — directly related to enstrophy $\frac{1}{2}\int |\omega|^2 dV$ via integration by parts and incompressibility. By the Beale–Kato–Majda regularity criterion combined with standard energy methods, monotonic control of this quantity in 3D would imply global smooth solutions for finite-energy initial data.

For the *ED-only NS* equation — the counterfactual obtained from full NS by removing the advective convective derivative —

$$\rho\, \partial_t v_i = \mu\nabla^2 v_i - \kappa\mu_{V1}\ell_P^2\nabla^4 v_i - \partial_i p, \qquad \nabla\cdot\mathbf{v} = 0,$$

the gradient-norm Lyapunov derivative computes as

$$\left.\frac{dL}{dt}\right|_{\text{ED-only NS}} = -\nu\int |\nabla^2 v|^2\, dV \;-\; \kappa\mu_{V1}\ell_P^2\int |\nabla^3 v|^2\, dV \;\leq\; 0,$$

with viscous diffusion contributing the standard $-\nu\|\nabla^2 v\|_2^2$ term and R1 contributing the additional $-\kappa\mu_{V1}\ell_P^2\|\nabla^3 v\|_2^2$ term via four integrations by parts on the ∇^4 operator. Pressure contributes zero by integration by parts combined with incompressibility.

Both contributions are manifestly non-positive. There are no positive terms in the ED-only NS gradient-norm Lyapunov derivative; the gradient norm is strictly monotonically decreasing along trajectories.

4.4 ED-only NS global smoothness

The ED-only NS equation with $\kappa > 0$ is a higher-derivative-regularized parabolic equation. Standard parabolic-regularity theory for this class (Lions 1969 and downstream literature) gives global smooth solutions for smooth, finite-energy initial data on $\mathbb{R}^3$. Specifically:

1. Local well-posedness in H^s for s sufficiently large.
2. Global H^s bound from the gradient-norm Lyapunov decay combined with the standard L^2 energy bound.
3. Bootstrap to higher regularity via repeated parabolic-regularity application; the ∇^4 regularization makes each step strictly stronger than standard NS.

This argument is canonical for higher-derivative-regularized parabolic equations and parallels global-smoothness results for the Navier–Stokes–Burgers equation. In our case, with the advective term entirely absent from ED-only NS, the smoothness result is *a fortiori* — the parabolic regularity machinery applies without the obstructive nonlinearity.

This establishes the **positive side of the Clay-relevance decomposition**: ED's architectural content alone, without the fluid-mechanical-addition advection, is sufficient for global smoothness on $\mathbb{R}^3$. The structural significance is that ED supplies a real, canon-level smoothing mechanism that would close the smoothness question in a fluid lacking advection.

---

5. The Advection Obstruction

5.1 Full NS + R1 gradient-norm derivative

When the advective convective derivative is restored to ED-only NS, full incompressible Navier–Stokes augmented with the R1 stabilization is recovered:

$$\rho\,\partial_t v_i + \rho\,(v\cdot\nabla)v_i \;=\; \mu\nabla^2 v_i - \kappa\mu_{V1}\ell_P^2\nabla^4 v_i - \partial_i p, \qquad \nabla\cdot\mathbf{v} = 0.$$

Computing dL/dt on this equation, three of four contributions are unchanged from the ED-only case: viscous diffusion contributes $-\nu\|\nabla^2 v\|_2^2 \le 0$; R1 contributes $-\kappa\mu_{V1}\ell_P^2\|\nabla^3 v\|_2^2 \le 0$; pressure contributes zero by integration by parts combined with incompressibility. The new contribution comes from advection.

5.2 The vortex-stretching term

The advective contribution to dL/dt reduces, after standard rearrangement using incompressibility, to the canonical vortex-stretching form:

$$\left(\frac{dL}{dt}\right)_{\text{adv}} \propto \int \omega\cdot(S\,\omega)\,dV,$$

where $\omega = \nabla\times\mathbf{v}$ is the vorticity and $S_{ij} = \frac{1}{2}(\partial_i v_j + \partial_j v_i)$ is the symmetric strain-rate tensor. This is the **vortex-stretching term** as it appears in standard turbulence-analysis texts. (Conventions for the proportionality constant vary across the literature based on whether L is defined with or without a factor of one-half and whether enstrophy or gradient-norm is used; the physical content of the indefinite-sign vortex-stretching contribution is convention-independent.)

5.3 Unique indefinite-sign contribution

In the aggregate dL/dt for full NS + R1,

$$\frac{dL}{dt} = \underbrace{-\nu\|\nabla^2 v\|_2^2}_{\leq 0} + \underbrace{-\kappa\mu_{V1}\ell_P^2\|\nabla^3 v\|_2^2}_{\leq 0} + \underbrace{0}_{\text{pressure}} + \underbrace{\int \omega \cdot S\omega \, dV \cdot (\text{const})}_{\text{indefinite}},$$

three terms are non-positive (viscous and R1 dissipative; pressure zero); only the advective vortex-stretching term has indefinite sign. **Any potential growth of the gradient norm in 3D NS + R1 must source from this term alone.** All other contributions to dL/dt are dissipative or neutral.

5.4 2D versus 3D contrast

The vortex-stretching term $\int \omega \cdot S\omega \, dV$ depends on the alignment of vorticity with strain-rate tensor eigenvectors. The strain S has three real eigenvalues $\lambda_1 \geq \lambda_2 \geq \lambda_3$ with $\lambda_1 + \lambda_2 + \lambda_3 = 0$ by tracelessness (incompressibility). Vorticity aligned with the λ_1-eigenvector gives positive integrand locally — vortex stretching amplifies vorticity. Vorticity aligned with the λ_3-eigenvector gives negative integrand locally — vortex compression diminishes vorticity. The integrated value is generically non-zero and indefinite-sign.

In two spatial dimensions, the situation is structurally different. Vorticity in 2D has only the out-of-plane component $\omega = \omega_z \hat{z}$, while the strain-rate tensor has only in-plane components. Therefore $\omega \cdot S\omega = 0$ identically — the vortex-stretching term vanishes in 2D.

This is the structural reason 2D NS has Leray-class global smooth solutions while 3D NS smoothness remains the open Clay problem. **The dimensional asymmetry between 2D and 3D in the smoothness question is not accidental; it is a direct consequence of the dimension-specific behavior of the advective vortex-stretching content.** ED's framework makes this asymmetry structurally intelligible: the obstruction to ED-style monotone gradient-norm decay vanishes in 2D and is sign-indefinite in 3D.

5.5 Localization of the obstruction

The aggregate finding of Section 5: **the advective convective derivative is the unique structural feature of full NS + R1 whose contribution to the gradient-norm Lyapunov derivative can have positive sign in 3D.** Pressure and incompressibility do not break the Lyapunov; they are dissipative-neutral. Viscous diffusion is dissipative. R1's substrate-scale stabilization is dissipative with sign FORCED positive. Only advection — specifically, its vortex-stretching content in 3D — produces indefinite-sign contributions.

The structural obstruction to closing Clay-NS via the R1 mechanism alone is therefore **localized at the advective term**. This sets up the architectural decomposition pursued in Section 7.

---

6. Three-Angle Convergence on Advection-is-Non-ED

6.1 Architectural convergence (NS-2.08)

The first lens identifying advection as structurally non-ED is architectural. NS-2.08 §5 catalogues the structural features of full NS that lie outside ED's canonical PDE channels. The catalogue identifies three fluid-mechanical additions: pressure as Lagrange multiplier, the advective convective derivative as kinematic coupling between velocity components, and the incompressibility constraint $\nabla \cdot \mathbf{v} = 0$ as a holonomic commitment. Of these three, advection

is the structural feature most strongly outside the canon: pressure and incompressibility have no architectural P-level counterparts but contribute zero to dynamical Lyapunov analyses (see Sections 4–5), while advection's kinematic coupling has no architectural P-level counterpart *and* contributes the indefinite-sign vortex-stretching content.

The architectural lens identifies advection as structurally non-ED because the kinematic-coupling structure of $(\mathbf{v} \cdot \nabla)\mathbf{v}$ has no analog among the canonical channels (mobility, penalty, participation). It is fluid-mechanical-specific structural content, not derivable from any canonical principle.

6.2 Dynamical convergence (NS-Smooth-3)

The second lens is dynamical. NS-Smoothness Section 5 (NS-Smooth-3 in the program memo system) computes the gradient-norm Lyapunov derivative for full NS + R1 explicitly and identifies the advective vortex-stretching term as the unique indefinite-sign contribution. Pressure contributes zero; viscous and R1 contributions are manifestly non-positive; only advection's vortex-stretching can drive growth of the gradient norm. The Lyapunov analysis localizes the obstruction at the advective term independently of the architectural-catalogue argument.

The dynamical lens identifies advection as structurally non-ED because it alone breaks the gradient-norm Lyapunov's monotonicity in 3D — a property that ED's R1 mechanism would otherwise enforce.

6.3 Spectral convergence (NS-Turb-4)

The third lens is spectral. NS-Turb's analysis of the P7 NS-turbulence-cascade mapping computes the Fourier-space interaction coefficient of the advective term and finds it to be

$$M_{ijm}(\mathbf{k}) = -ik_j P_{im}(\mathbf{k}), \qquad P_{im}(\mathbf{k}) = \delta_{im} - \frac{k_i k_m}{k^2},$$

with transport-directional structure (via k_j) and incompressibility projection (via P_{im}). This index structure is *asymmetric* and *transport-directional* — fundamentally different from ED's P7 nonlinearity, which is symmetric quadratic-in-gradients $M'(\rho)|\nabla\rho|^2$ at the canonical-PDE level. The advective bilinear-with-projection structure cannot be absorbed into P7-class symmetric-quadratic Fourier mapping.

The spectral lens identifies advection as structurally non-ED because its index structure is incompatible with the canonical nonlinear-coupling form provided by P7.

6.4 Robustness across analytical frameworks

The three lenses operate at three different mathematical levels — architectural canon-membership, dynamical Lyapunov-derivative-sign, and spectral Fourier-mode-coupling — and use disjoint analytical machinery. Yet each identifies the same physical feature (advection's transport-directional, asymmetric, projected index structure) as the locus of the ED NS structural mismatch.

The independence of the three lenses is essential. If only one analysis identified advection as non-ED, the finding would be susceptible to the suspicion that the analytical framework itself was unsuited to the question. Three independent frameworks identifying the same feature establishes the finding as structural rather than methodological — robust across analytical lenses.

This three-angle convergence is the most consistent and load-bearing structural finding in the ED Navier–Stokes program. It is invoked in Section 7 as the load-bearing input for the Intermediate Path C verdict.

---

7. Intermediate Path C (Clay-Relevance)

7.1 R1 positive side

ED's canonical architectural content supplies a real Clay-NS-relevant regularizing mechanism. The R1 mechanism — the form-FORCED $-\kappa\mu_{V1}\ell_P^2\nabla^4 v$ stabilization arising from V1's finite-width vacuum kernel under multi-scale expansion — combined with standard viscous diffusion produces, in the counterfactual ED-only NS lacking the advective term, a strictly monotonically-decaying gradient-norm Lyapunov:

$$\left.\frac{dL}{dt}\right|_{\text{ED-only NS}} = -\nu\|\nabla^2 v\|_2^2 - \kappa\mu_{V1}\ell_P^2\|\nabla^3 v\|_2^2 \;\leq\; 0.$$

By standard parabolic-regularity theory, ED-only NS has global smooth solutions on $\mathbb{R}^3$ for finite-energy initial data. *If* 3D Navier–Stokes lacked the advective convective derivative, ED's architectural content would unconditionally close the Clay-NS smoothness question.

7.2 Advection negative side

The actual obstruction to closing Clay-NS in 3D is the advective convective derivative's vortex-stretching content $\int \omega \cdot S\omega \, dV$, which is the unique indefinite-sign contribution to dL/dt in full NS + R1. This term vanishes identically in 2D (where vortex-stretching does not exist) and is sign-indefinite in 3D.

The advective term is structurally non-ED at three independent program-level analyses (Section 6): architectural (advection is fluid-mechanical addition not native to canonical channels), dynamical (advection alone breaks the gradient-norm Lyapunov via vortex-stretching), and spectral (advection's bilinear-with-projection Fourier structure is incompatible with P7-class symmetric-quadratic mapping). The three-angle convergence makes the advection-as-non-ED finding robust across analytical lenses.

7.3 Structural decomposition of smoothness difficulty

The two sides combine into the **Intermediate Path C structural decomposition**:

Component	Source	Sign	Status
Viscous diffusion $-\nu\|\nabla^2 v\|^2$	Standard NS	Dissipative (≤ 0)	Standard
R1 stabilization $-\kappa\mu_{V1}\ell_P^2\|\nabla^3 v\|^2$	ED canonical	Dissipative (≤ 0); sign FORCED	Form-FORCED ED architecture
Pressure	Lagrange multiplier	Zero	Fluid-mechanical addition
Advection vortex-stretching	Fluid-mechanical addition	Indefinite-sign	Non-ED (three-angle convergence)

The decomposition makes the Clay-NS difficulty intelligible. ED supplies real *regularizing infrastructure* (R1), form-FORCED, sign-FORCED-positive, dissipative. The structural feature

breaking gradient-norm monotonicity in 3D is *not* in ED's canonical content; it is the fluid-mechanical-specific advective coupling. The *quantitative competition* between R1's dissipative content (dominant only at substrate scales $\sim \ell_P$) and advective vortex-stretching (active at intermediate scales between flow scale and substrate) determines whether smoothness preserves or breaks. **This competition is INHERITED on both sides** — depends on V1's specific G-function profile (inherited per arc-N N.4) and on standard kinetic-theory super-Burnett magnitude (inherited via material kinetic parameters). Neither magnitude is canonically fixed; therefore neither is the dominant in any specific blow-up scenario.

7.4 What ED explains

The structural decomposition explains:

- **Why the Navier–Stokes form appears.** NS reproduces from substrate primitives via two concordant routes; the viscous content is canonical ED architecture.
- **Why 2D NS is globally smooth.** Vortex-stretching vanishes identically in 2D; the gradient-norm Lyapunov is monotone-decreasing exactly as in ED-only NS.
- **Why 3D NS smoothness is structurally hard.** The obstructing structural feature lies outside ED's canonical regularizing architecture; the canon does not natively absorb advection.
- **Where the obstruction is localized.** Uniquely at the advective convective derivative — confirmed at three independent analytical levels.
- **Why R1's substrate-scale stabilization is real but not unconditionally sufficient.** R1 is form-FORCED and sign-FORCED-positive, but its coefficient is INHERITED at the value level and the term is suppressed at intermediate scales where advective vortex-stretching is most active.

7.5 What ED does not explain

The structural decomposition does not deliver:

- **Whether 3D NS solutions blow up at finite time or remain smooth globally.** The Clay-NS open question remains open; ED does not resolve which side wins quantitatively.
- **Numerical critical Reynolds numbers** for any specific transition (laminar-to-turbulent, pipe flow Re_c 2300, boundary-layer transition, etc.).
- **Specific blow-up criteria** beyond the Beale–Kato–Majda framework.
- **The detailed cascade structure** of developed turbulence (Kolmogorov 5/3 spectrum, intermittency exponents, anomalous scaling).

ED's contribution to the Clay-NS question is **structural-decompositional, not quantitative-resolutional**. This is the substantive Intermediate Path C content. The framework neither solves Clay-NS nor is irrelevant to it; it provides a partial structural framework that explains why the difficulty exists where it does without resolving how the difficulty plays out quantitatively.

---

8. Turbulence

8.1 H1 trivial

The first hypothesis tested in the NS-Turb arc is H1: ED's P7 nonlinear-triad-coupling structure shares generic triadic Fourier structure with the NS turbulent cascade. This succeeds trivially. Both P7's harmonic generation $M'(\rho)|\nabla\rho|^2$ and NS's advective term $(\mathbf{v}\cdot\nabla)\mathbf{v}$ produce triadic Fourier interactions $\mathbf{k}_1 + \mathbf{k}_2 + \mathbf{k}_3 = 0$ — momentum conservation in mode-mode interactions.

This is generic to any quadratic-or-higher-in-field nonlinearity in Fourier space; it carries no ED-specific architectural insight beyond "NS has a quadratic nonlinearity."

H1 closure: succeeds trivially; provides no ED-specific structural content beyond the generic Fourier-triadic structure.

8.2 H2 partial

The second hypothesis tested is H2: ED's canonical 3–6% P7 amplitude ratio (Universal Invariants §3) corresponds to a specific turbulence-cascade observable. This succeeds *partially* in a restricted regime.

In the inertial range of developed turbulence, dimensionless triad-transfer observables (fractional transfer per eddy turnover, normalized triad correlation coefficient) have values $\tilde{f} \sim 0.1$–0.3 for active cascade triads — 2 to 10 times larger than P7's 3–6%. H2 fails in the cascade regime.

In the *forced-response* regime of viscous-laminar single-wavenumber-forced flow, by contrast, weakly-nonlinear analysis gives a third-harmonic amplitude ratio

$$R_{\text{forced}} = \frac{|u(3k_0)|}{|u(k_0)|} \sim \varepsilon^2,$$

with $\varepsilon = u(k_0)/(\nu k_0)$ a dimensionless forcing-mode parameter. For moderate weakly-nonlinear $\varepsilon \sim 0.15$–0.3, R_{forced} falls in the range 0.02–0.09 — overlapping P7's 3–6% range cleanly.

H2 holds in this restricted forced-response regime as a substantive but limited correspondence. The match is at order-of-magnitude / window-overlap level rather than at precise-prefactor level, and it does not extend to the developed-cascade regime that defines turbulence empirically. The match is **coincidental rather than structural** — both phenomena have triadic Fourier structure with weak coupling, producing similar amplitude scaling in the appropriate regimes, but the underlying dynamics differ in mechanism (driven vs. cascade), polynomial order (cubic vs. bilinear), and index structure (symmetric-gradient vs. transport-directional).

8.3 H3 fail

The third hypothesis tested is H3: ED's P7 supplies an architectural template for the developed-cascade turbulence structure of 3D NS. This fails. Three structural mismatches prevent P7 from templating the cascade:

1. **Mechanism mismatch.** P7 is forced harmonic generation by external driving on a fundamental; turbulence cascade is free conservative redistribution across modes. The triadic conservation identity $S(\mathbf{k}|\mathbf{p},\mathbf{q}) + S(\mathbf{p}|\mathbf{q},\mathbf{k}) + S(\mathbf{q}|\mathbf{k},\mathbf{p}) = 0$ holds in the inertial range, distinguishing free-cascade physics from driven harmonic-generation physics.

2. **Polynomial-order mismatch.** P7 nonlinearity is cubic in field (third harmonic at first nonlinear order); NS advection is bilinear in field (third harmonic at second nonlinear order). Same numerical magnitude requires different effective forcing intensities.

3. **Index-structure asymmetry.** P7 is symmetric quadratic-in-gradients; NS advection is bilinear field-times-gradient with directional transport and incompressibility projection. The asymmetry persists at all amplitudes.

H3 fails. ED's P7 does not architecturally template developed-cascade turbulence.

8.4 Spectral incompatibility with P7

The deepest finding from NS-Turb is the spectral incompatibility of the advective interaction coefficient with P7-class structure. Computing the NS triadic interaction coefficient explicitly,

$$M_{ijm}(\mathbf{k}) = -ik_j P_{im}(\mathbf{k}),$$

with transverse projector $P_{im}(\mathbf{k}) = \delta_{im} - k_i k_m/k^2$ enforcing incompressibility, reveals a transport-directional, asymmetric, projected structure. P7's nonlinearity in Fourier space, by contrast, produces a symmetric-in-permutation interaction coefficient appropriate to gradient self-coupling. The two are structurally different; no constitutive choice for $M(\rho)$ in P7 produces the transport-directional content of NS advection.

The spectral incompatibility is the third angle in the three-angle convergence on advection-as-non-ED (Section 6).

8.5 Why ED has no turbulence-cascade template

The aggregate verdict of NS-Turb is that **ED's canonical content does not architecturally template developed-cascade turbulence**. The cascade dynamics — the substantive content of "what makes turbulence turbulence" — is built on the advective vortex-stretching mechanism, which is non-ED at architectural, dynamical, and spectral levels. ED's contribution to fluid mechanics in the turbulence regime is therefore limited:

- **Forced-response harmonic generation** in viscous-laminar regime: ED-architectural restricted-regime prediction (H2 partial).
- **Cascade structure** (Kolmogorov spectrum, intermittency, anomalous scaling): no ED-architectural prediction (H3 fail).
- **Smoothness / blow-up** (Clay-NS): Intermediate Path C; obstruction is the same advective vortex-stretching that NS-Turb identifies as breaking P7-class structure.

The three program-level findings — Architectural Canon Vector Extension's catalogue of advection as non-ED, NS-Smoothness's localization of the gradient-norm Lyapunov obstruction, and NS-Turb's spectral incompatibility — are mutually reinforcing. The same structural feature is the locus of ED's bounded reach into Navier–Stokes phenomena.

---

9. Synthesis

9.1 Unified structural picture

The five closed Navier–Stokes arcs assemble into a coherent unified structural picture. Event Density's relationship to classical fluid mechanics is neither one of identity nor of irrelevance: it is partial and structurally honest.

- **Form derivation:** the Navier–Stokes form follows from substrate primitives via two concordant routes (NS-2). Both routes produce the same Newtonian-fluid form.
- **Dimensional forcing:** the spatial dimension D = 3+1 is forced by ED's framework when combined with observed gravity (NS-1, Path B-strong).
- **Architectural classification:** NS is partially ED-architectural — its viscous content is canonical ED vector-extended; its pressure, advection, and incompressibility content is fluid-mechanical-specific structural addition (NS-2.08 catalogue).

- **Clay-relevance:** ED contains a real, form-FORCED regularizing mechanism (R1) that closes ED-only NS smoothness unconditionally and that is suppressed but structurally present in full NS (NS-3 + NS-Smoothness).
- **Turbulence cascade:** no architectural template; the cascade mechanism is non-ED (NS-Turb).
- **Three-angle convergence:** advection is structurally non-ED at architectural, dynamical, and spectral levels independently — the most robust structural finding in the program.

9.2 ED's position relative to classical Navier–Stokes

The unified picture positions ED relative to classical NS as follows. Classical NS is a phenomenological framework: it postulates the equation form, takes the dimensional structure as observational, and treats the smoothness question as an open mathematical problem. ED is an architectural framework: it derives the equation form (partly), forces the dimensional structure, and decomposes the smoothness question into a part it explains (the regularizing infrastructure) and a part it does not (the advective obstruction). The two frameworks agree on observational content — ED reproduces standard Newtonian-fluid NS at NS scales — and differ on structural origin.

Classical NS is the empirically successful phenomenology. ED is the architectural account underneath that phenomenology, exposing which structural features are forced by substrate-level commitments and which are fluid-mechanical-specific additions inherited from the kinematic structure of incompressible flow.

9.3 ED's architectural reach and limits

The reach of ED's architectural content into Navier–Stokes phenomena is substantial but bounded. The canonical canon delivers the viscous content of NS, the dimensional structure D = 3+1, the substrate-cutoff regularization R1, the gradient-norm Lyapunov for ED-only NS, the 2D-versus-3D smoothness asymmetry, and the structural localization of the Clay obstruction. These are all forced theorems of the architectural canon plus its vector-extension.

The canon does not deliver Clay-NS resolution, critical Reynolds numbers, turbulence cascade architecture, or specific blow-up criteria. These lie outside the architectural reach. The boundary of ED's architectural content is itself structurally identified: it is the boundary of what the canonical principles P1–P7 plus the partial vector-extension framework can absorb. Advection lies outside this boundary at three independent levels.

This honest delineation of reach and limits is the substantive structural content of the synthesis: ED is a partial architectural account of NS, with the boundary of its reach explicitly identified and characterized.

9.4 Relationship to the P4-NN rheology paper

This synthesis paper covers the foundational structural content of ED's relationship to Navier–Stokes — form derivation, dimensional forcing, Clay-relevance decomposition, turbulence verdict. The companion P4-NN paper (*ED Mobility Saturation Predicts Non-Newtonian Rheology*) covers the empirical-applications content of ED's reach into non-Newtonian fluid mechanics: Krieger–Dougherty divergence, discontinuous shear-thickening, Cross/Carreau shear-thinning, Maxwell-class viscoelasticity, and the canonical $\beta = 2.0$ exponent prediction supported within 1σ by the Universal Mobility Law's ten-system empirical anchor.

The two papers together cover the program's published-grade content on classical fluids: foundational structural questions in this paper, empirical applications in P4-NN. They share ar-

chitectural content (the same canonical canon, the same form-FORCED / value-INHERITED methodology) but address different levels of the fluid-mechanics hierarchy. Both are grounded in the same Universal Mobility Law $D(c) = D_0(1-c/c_{\max})^\beta$ — the same architectural principle (P4 mobility capacity bound) that produces non-Newtonian rheology classes empirically also produces, in the NS context, the dissipative content of the Newtonian viscous term.

The two papers complement, not replace, each other.

---

10. Conclusion

10.1 Summary

We have presented a unified architectural account of the Navier–Stokes equations within the Event Density program. From substrate-level commitments, the canonical PDE's vector-extension produces the viscous content of standard Newtonian-fluid NS, with the dimensional structure D = 3+1 forced via a Path B-strong argument combining architectural and empirical-consistency lines. Substrate-level coarse-graining of chain dynamics produces the same NS form via a methodologically distinct route, and the two derivations are concordant. Pressure, the advective convective derivative, and the incompressibility constraint are catalogued explicitly as fluid-mechanical-specific structural additions not native to ED canonical channels.

The architectural canon supplies a real, form-FORCED regularizing mechanism — the R1 substrate-scale stabilization arising from V1's finite-width vacuum kernel — that produces, in the counterfactual ED-only NS lacking advection, strictly monotonically-decaying gradient-norm Lyapunov decay and global smooth solutions on $\mathbb{R}^3$. The advective vortex-stretching content of full 3D NS is the unique structural feature whose contribution to the gradient-norm Lyapunov derivative can be sign-indefinite; it vanishes identically in 2D, accounting for the dimensional asymmetry of NS smoothness. Three independent program-level analyses (architectural, dynamical, spectral) converge on advection as structurally non-ED — the most robust structural finding in the program.

The Intermediate Path C verdict follows: ED neither solves the Clay-NS smoothness problem nor is irrelevant to it. ED supplies a partial structural framework that explains why the difficulty exists where it does, decomposing the Clay-NS question into ED-canonical regularizing infrastructure plus non-ED structural obstruction. The decomposition explains the 2D-versus-3D smoothness asymmetry, localizes the 3D obstruction at the advective term, and is robust across architectural, dynamical, and spectral lenses. It does not resolve which side wins quantitatively; that competition is INHERITED on both sides.

The closure of NS-Turb at H1 trivial / H2 partial / H3 fail establishes that ED supplies no architectural template for developed-cascade turbulence. The cascade mechanism is built on the advective vortex-stretching content that the three-angle convergence identifies as non-ED. The reach of ED's architectural content into Navier–Stokes phenomena is therefore substantial but bounded: it covers form derivation, dimensional forcing, structural smoothness decomposition, and the 2D-versus-3D asymmetry; it does not cover Clay-NS resolution, critical Reynolds numbers, or turbulence cascade architecture.

10.2 Future directions

Three concrete directions emerge as candidate future arcs:

- **Path A B2 promotion via diffusion-coarse-graining theorem.** NS-1.03's identification gap (chain-dynamics-as-diffusion at coarse-grained scale) would close if a primitive-

level coarse-graining-to-diffusion theorem for ED chain dynamics were established. This would promote NS-1's architectural-suggestive d 3 to a strict architectural theorem.

- **Path C+ promotion via R1-versus-Burnett quantitative dominance.** NS-3's Intermediate Path C verdict could promote toward Path C+ (clean Clay-NS resolution) if a structural argument established R1's substrate-scale stabilization as quantitatively dominant over standard kinetic-theory super-Burnett destabilization through scales. This is value-level work depending on parameters INHERITED on both sides.
- **Tensor-extension of the Architectural Canon.** Rheology classes that are non-canonical at the current canon (Oldroyd-B, Giesekus, FENE-P) require conformation-tensor structure beyond the canonical scalar PDE. A formal tensor-extension parallel to the vector-extension framework would absorb these into ED's architectural reach.

Each is substantive future work, parallel in scope to the closed arcs of the present paper. None is required for the Intermediate Path C verdict.

10.3 Program-level implications

This paper closes the structural-foundations content of the Event Density program's relationship to Navier–Stokes. With the closure of NS-1, NS-2, NS-3, NS-Smoothness, and NS-Turb, the program has a complete picture of how ED relates to classical fluid mechanics, the Clay-NS smoothness problem, and the structural status of turbulence. Combined with the empirical-applications content of the P4-NN companion paper, the program's published-grade fluid-mechanics content is now consolidated.

The framework's posture is the same as in the broader ED program: substrate primitives plus structural canon principles produce, as forced theorems, the foundational structures of nominally separate domains of physics. For Navier–Stokes the result is partial — the canon supplies the viscous content and the dimensional forcing; advection is identified as structurally outside the canon. The boundary of ED's reach is itself structurally identified, not hand-waved. That honest delineation of reach and limits is the substantive contribution of the synthesis.

Whether the structural decomposition presented here becomes part of a future Clay-NS resolution, or whether the Clay-NS question is resolved by methods entirely outside ED's architectural framework, is an empirical-mathematical question that future analytical work must answer. ED's case is on the table.

Appendix A — Key Equations

For reference, the load-bearing equations of the synthesis are collected here.

Canonical Event Density PDE:

$$\partial_t \rho = D \cdot F[\rho] + H \cdot v, \qquad F[\rho] = M(\rho)\nabla^2\rho + M'(\rho)|\nabla\rho|^2 - P(\rho).$$

ED-only NS equation (counterfactual; without advection):

$$\rho\, \partial_t v_i = \mu\nabla^2 v_i - \kappa\mu_{V1}\ell_P^2\nabla^4 v_i - \partial_i p, \qquad \nabla\cdot\mathbf{v} = 0.$$

Full Navier–Stokes with R1 stabilization:

$$\rho\, \partial_t v_i + \rho\,(v\cdot\nabla)v_i = \mu\nabla^2 v_i - \kappa\mu_{V1}\ell_P^2\nabla^4 v_i - \partial_i p, \qquad \nabla\cdot\mathbf{v} = 0.$$

Gradient-norm Lyapunov:

$$L(t) = \frac{1}{2}\|\nabla \mathbf{v}(t)\|_2^2.$$

Gradient-norm Lyapunov derivative for ED-only NS:

$$\left.\frac{dL}{dt}\right|_{\text{ED-only NS}} = -\nu \int |\nabla^2 v|^2 \, dV - \kappa \mu_{V1} \ell_P^2 \int |\nabla^3 v|^2 \, dV \leq 0.$$

Gradient-norm Lyapunov derivative for full NS + R1:

$$\frac{dL}{dt} = -\nu \|\nabla^2 v\|_2^2 - \kappa \mu_{V1} \ell_P^2 \|\nabla^3 v\|_2^2 + 0 + \int \omega \cdot S\omega \, dV \cdot (\text{const}).$$

Vortex-stretching contribution (advective):

$$\left(\frac{dL}{dt}\right)_{\text{adv}} \propto \int \omega \cdot (S\,\omega) \, dV.$$

NS triadic interaction coefficient (Fourier space):

$$M_{ijm}(\mathbf{k}) = -ik_j P_{im}(\mathbf{k}), \qquad P_{im}(\mathbf{k}) = \delta_{im} - \frac{k_i k_m}{k^2}.$$

Forced-response third-harmonic ratio (NS-Turb-3):

$$R_{\text{forced}} = \frac{|u(3k_0)|}{|u(k_0)|} \sim \varepsilon^2, \qquad \varepsilon = \frac{u(k_0)}{\nu k_0}.$$

Appendix B — Summary of Closed Navier–Stokes Arcs

Arc	Headline	Status
NS-1	D = 3+1 forced via Path B-strong (architectural d 3 + architectural-suggestive d 3 + empirical-consistency d 3)	Closed
NS-2	Standard Newtonian-fluid NS form derived via two concordant routes (chain-substrate + ED-PDE-direct); advection / pressure / incompressibility flagged as fluid-mechanical additions	Closed

Arc	Headline	Status
NS-3	Intermediate Path C: ED contains real Clay-relevant R1 mechanism (form-FORCED $-\kappa\mu_{V1}\ell_P^2\nabla^4 v$); quantitative competition vs. super-Burnett INHERITED	Closed
NS-Smoothness	Clay-relevance decomposition: R1 + advection-obstruction; ED-only NS has $dL/dt \leq 0$; advective vortex-stretching is unique indefinite-sign contribution in full NS + R1; three-angle convergence on advection-is-non-ED	Closed
NS-Turb	H1 trivial / H2 partial (forced-response regime, $\varepsilon \sim 0.15$–0.3) / H3 fail; no architectural template for developed-cascade turbulence	Closed

---

Appendix C — Architectural Canon References

- **P1 (operator structure):** $F[\rho] = M(\rho)\nabla^2\rho + M'(\rho)|\nabla\rho|^2 - P(\rho)$.
- **P2 (channel complementarity):** $\partial_t\rho = D \cdot F[\rho] + H \cdot v$, $D + H = 1$.
- **P3 (penalty equilibrium):** $P(\rho^*) = 0$, $P'(\rho^*) > 0$, monostable.
- **P4 (mobility capacity bound):** $M(\rho_{\max}) = 0$, $M(\rho) > 0$ for $\rho < \rho_{\max}$.
- **P5 (participation feedback):** $\dot{v} = \tau^{-1}(\bar{F}(\rho) - \zeta v)$.
- **P6 (damping discriminant):** $D_{\text{crit}}(\zeta) \approx 0.896$ at $\zeta = 1/4$.
- **P7 (nonlinear triad coupling):** harmonic generation at canonical 3–6% from $M'(\rho)|\nabla\rho|^2$.

The Architectural Canon Vector Extension establishes that P1–P7 are field-type-agnostic at architectural level; vector and tensor field PDEs satisfying P1–P7 component-wise are architecturally ED. C5 (single scalar field) binds at the concrete-PDE-level canonical exemplar but not at the P-level architectural canon. The three-tier classification distinguishes canonical / fully ED-architectural / partially ED-architectural PDEs.

Event Density is an open research framework being developed publicly by independent physicist Allen Proxmire. The full technical program — primitives, derivations, simulations, twenty-one forced theorems plus the ED Combination Rule, and pre-registered experimental tests across three domains — is available at github.com/allen-proxmire, with archival DOIs through Zenodo. The complete Navier–Stokes program memos (NS-1 through NS-Turb-5) are in the program repository under theory/Navier Stokes/. April 2026.

Appendix C — MHD Extension and ED-I-06 Ontological Integration

Companion appendix to The Architectural Foundations of Navier-Stokes in Event Density: Form Derivation, Clay-Relevance Decomposition, and the Structural Status of Turbulence.

C.1 Purpose

This appendix extends the architectural account of the main paper in two complementary directions.

First, it extends the NS architectural classification (Sections §3–§6 of the main paper) to **incompressible magnetohydrodynamics (MHD)**, the canonical theory of electrically conducting fluids that couples Navier-Stokes to Maxwell's equations through Ohm's law and the induction equation. The appendix shows that the canonical / non-canonical boundary established for pure NS generalizes cleanly to MHD, with two structural refinements: every electromagnetic-side addition introduced by the MHD upgrade is ED-canonical, and the new fluid-mechanical-specific structural commitments (induction-equation kinematic term, Ohm's-law kinematic component) belong to a single transport-kinematic class shared with NS advection.

Second, it integrates the **ED-I-06 *Fields and Forces* ontology** (Proxmire, *Fields and Forces in Event Density*, 2026) as the conceptual framework that explains *why* the canonical / non-canonical boundary lives where it does. The ED-I-06 ontology supplies a forces-vs-frame-

kinematic reading under which the structural classifications of NS-2.08, NS-Smoothness, NS-Turbulence, and the MHD arc all read as instances of a single ontological distinction.

The appendix delivers a final architectural classification table covering all eleven content items of the standard incompressible MHD system, with both structural and ontological status indicated for each. The main results of the NS Synthesis Paper remain unchanged; the ontological integration provides ED-I-06-grounded framing for those results without revising any technical conclusion.

C.2 ED-I-06 Ontology: Forces, Fields, and Participation Structures

ED-I-06 reframes fields and forces in terms of stable participation structures. Three structural classes of field-like participation arise naturally from the internal organization of participation channels:

- **Directional fields** — channels with a preferred orientation. ED-I-06 cites magnetic structure, spin textures, and *vorticity-like fluid structures* explicitly (§3). In the NS / MHD context, the velocity field $\mathbf{v}$, the vorticity ω, the magnetic field $\mathbf{B}$, and the gauge field A_μ (formalized as τ_g's participation measure under T17) are all directional fields.
- **Scalar fields** — gradients in participation density. Pressure p and mass density ρ in fluid mechanics, electric and chemical potentials, energy landscapes — all are emergent properties of how participation density varies across space (ED-I-06 §4).
- **Curvature-like fields** — pre-geometric participation patterns where propagation paths are biased in geometric-bending-like ways. ED-I-06 §5 designates this class as the conceptual bridge to spacetime emergence in ED-10. Substrate-gravity content (Theorems 19, 20, ED Combination Rule, T21) belongs to this class at substrate level.

Forces. ED-I-06 defines forces as **biases in participation flow sourced by stable participation structures** (§6). The underlying principle: *micro-events follow the most stable participation channels available to them.* When directional, scalar, or curvature-like structures bias propagation, the system experiences what is conventionally interpreted as a force.

Non-forces. Two structurally distinct classes of non-force content can appear in continuum equations:

- **Transport-kinematic frame terms** — bilinear couplings between transport fields that arise specifically when dynamics are written in a fluid (Eulerian) coordinate system. These are coordinate-frame artifacts of the fluid description, not biases sourced by stability.
- **Continuum-imposed constraints** — fluid-mechanical structural commitments (incompressibility, pressure as Lagrange multiplier) imposed at continuum level rather than sourced by participation structure.

The key ontological boundary is:

> *Canonical ED content corresponds to forces from participation structures.*
>
> *Non-ED content corresponds to transport-kinematic frame terms and continuum constraints.*

This single boundary unifies six previously separate findings of the NS / MHD program:

- **NS-2.08** classified advection, pressure, and incompressibility as fluid-mechanical-additions not native to ED canonical channels.

- **NS-Smoothness** (Section §5 of the main paper) identified the advective vortex-stretching $\int \omega \cdot S\omega \, dV$ as the unique indefinite-sign contribution to the gradient-norm Lyapunov in 3D NS.
- **NS-Turbulence** (Section §6 of the main paper) found the NS advective triad to be spectrally incompatible with P7's symmetric quadratic class.
- **NS-MHD-2** identified the Lorentz force as canonical ED via T17 minimal coupling, with the kinematic $\mathbf{v} \times \mathbf{B}$ component derived from the minimal-coupling form rather than separately committed.
- **NS-MHD-3** established three-angle convergence on the induction-equation kinematic term as non-ED at architectural / dynamical / spectral levels — the magnetic-side analogue of NS advection.
- **NS-MHD-4** consolidated the eleven-item architectural classification of incompressible MHD.

Under the ED-I-06 ontology, all six findings read as instances of the single forces-vs-frame-kinematic distinction. The transport-kinematic class (advection, induction kinematic, Ohm kinematic) consists of frame artifacts of the fluid coordinate system; the canonical-ED class (viscous diffusion, magnetic diffusion, Lorentz force, Maxwell structure, R1 substrate cutoff) consists of biases sourced by stable participation structures (directional fields, the V1 vacuum kernel, the gauge directional-field τ_g).

C.3 The Incompressible MHD System

The standard incompressible resistive MHD equations couple Navier-Stokes to Maxwell's equations via the Lorentz force in the momentum equation and the induction equation for the magnetic field:

Momentum equation:

$$\rho(\partial_t \mathbf{v} + (\mathbf{v} \cdot \nabla)\mathbf{v}) = -\nabla p + \mu \nabla^2 \mathbf{v} + (\nabla \times \mathbf{B}) \times \mathbf{B} + \rho \mathbf{f}^{\text{ext}}.$$

Induction equation:

$$\partial_t \mathbf{B} = \nabla \times (\mathbf{v} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B}.$$

Constraints:

$$\nabla \cdot \mathbf{v} = 0, \qquad \nabla \cdot \mathbf{B} = 0.$$

The Lorentz force per unit volume in the MHD limit is $\mathbf{j} \times \mathbf{B} = \mu_0^{-1}(\nabla \times \mathbf{B}) \times \mathbf{B}$, with quasi-neutrality suppressing the $\rho_q \mathbf{E}$ contribution at typical MHD scales. The magnetic diffusivity is $\eta = 1/(\sigma\mu_0)$, with σ the electrical conductivity. The **ED-augmented momentum equation** carries an additional R1 term $-\kappa\mu_{\text{V1}}\ell_P^2\nabla^4\mathbf{v}$ inherited from the velocity sector (§4 of the main paper, NS-3.01 / NS-Smoothness-2):

$$\rho(\partial_t \mathbf{v} + (\mathbf{v} \cdot \nabla)\mathbf{v}) = -\nabla p + \mu \nabla^2 \mathbf{v} - \kappa\mu_{\text{V1}}\ell_P^2\nabla^4\mathbf{v} + (\nabla \times \mathbf{B}) \times \mathbf{B} + \rho \mathbf{f}^{\text{ext}}.$$

The generalized resistive Ohm's law is

$$\mathbf{j} = \sigma(\mathbf{E} + \mathbf{v} \times \mathbf{B}).$$

Its $\mathbf{v} \times \mathbf{B}$ piece is a transport-kinematic component classified alongside the induction kinematic term.

This eleven-item content set covers every term in standard incompressible resistive MHD. The classification that follows is over these eleven items.

C.4 Architectural Classification of MHD Terms

The four sub-arc memos NS-MHD-1 through NS-MHD-5 jointly classify every MHD content channel. Three classes emerge.

C.4.1 Canonical ED content (6 items)

Each item is FORCED at form level by a canonical ED channel and is ontologically a force sourced by a stable participation structure:

(a) Viscous diffusion $\mu\nabla^2\mathbf{v}$. The mobility channel applied component-wise to velocity. Per the field-type-agnostic vector-extension of the canonical PDE (Architectural Canon Vector Extension memo), the mobility channel produces a Laplacian-class diffusion structure on any vector field at fluid scale. Ontologically, $\mu\nabla^2\mathbf{v}$ is a participation-flow bias toward smoother velocity orientation, sourced by the directional-field structure of $\mathbf{v}$ itself. Form FORCED; coefficient μ INHERITED at value layer.

(b) Magnetic diffusion $\eta\nabla^2\mathbf{B}$. The mobility channel applied component-wise to the magnetic field. Structurally identical to (a) at the level of canonical-channel derivation — the vector-extension is field-type-agnostic, so the same mobility-channel argument that produces $\mu\nabla^2\mathbf{v}$ produces $\eta\nabla^2\mathbf{B}$. Ontologically, a participation-flow bias on the magnetic directional field. Form FORCED; resistivity $\eta = 1/(\sigma\mu_0)$ INHERITED.

(c) Lorentz force $(\nabla \times \mathbf{B}) \times \mathbf{B}$. Theorem 17 (Gauge-Fields-as-Rule-Type) FORCES the substrate-level minimal-coupling form $\partial_\mu \to \partial_\mu - iqA_\mu$ on charged structural rule-types. The classical semiclassical limit yields the per-chain force $q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$; coarse-graining to fluid scale yields the force density $\rho_q\mathbf{E} + \mathbf{j} \times \mathbf{B}$, which reduces in the MHD limit to $(\nabla \times \mathbf{B}) \times \mathbf{B}$. Ontologically, the bias on charged-chain participation flow imposed by the gauge directional-field τ_g. Form FORCED by T17 minimal coupling; the kinematic $\mathbf{v} \times \mathbf{B}$ component is *derived* from the minimal-coupling form rather than separately committed (NS-MHD-2 §3.2). Coarse-graining bridge INHERITED in parallel to the NS-2 viscous-content coarse-graining.

(d) Maxwell field structure ($\partial_t\mathbf{B}$, $\nabla \times \mathbf{B}$, $\nabla \cdot \mathbf{B} = 0$). Theorem 17's gauge content directly FORCES the four-channel structure of τ_g (group, vertex, worldline, vacuum), from which Maxwell's equations follow under gauge-quotient identification. The magnetic-divergence-free constraint $\nabla \cdot \mathbf{B} = 0$ is the no-monopoles structural feature of the canonical $U(1)$ gauge content — distinct in status from the velocity incompressibility constraint (which is fluid-mechanical-imposed). Ontologically, directional-field dynamics for τ_g. Form FORCED; field amplitudes INHERITED.

(e) R1 substrate-cutoff term $-\kappa\mu_{\mathrm{V1}}\ell_P^2\nabla^4\mathbf{v}$. The form-FORCED hyperviscous stabilization arising from V1's finite-width vacuum kernel (Section §5 of the main paper). Inherits into the MHD momentum equation by virtue of being a canonical-ED augmentation of the velocity sector independent of EM coupling. Ontologically, a substrate-level participation-stability mechanism (T18-class kernel retardation expressed at V1 vacuum-kernel scale) imposing a hyperviscous bias on velocity-gradient cascade. Form FORCED; coefficient κ INHERITED.

All six items are forces in the ED-I-06 sense — biases on participation flow sourced by stable participation structures.

C.4.2 Continuum constraints (non-obstructive, 2 items)

These items are not forces in the ED-I-06 sense and are not derivable from any canonical ED channel. They are continuum-level structural commitments imposed at fluid scale rather than sourced by participation structure. Crucially, they are also *non-obstructive*: they introduce no indefinite-sign Lyapunov contributions and no spectral pathology.

(f) Pressure $-\nabla p$. Scalar-gradient in form (the gradient of a scalar density-class quantity) but *imposed* as a Lagrange multiplier for the incompressibility constraint, not sourced as a participation-density bias from below. Ontologically, a constraint-derived field rather than a force-from-stability. Sign-definite contribution to the kinetic-energy budget.

(g) Velocity incompressibility $\nabla \cdot \mathbf{v} = 0$. Continuum kinematic constraint, not derivable from any canonical channel. The canonical ED PDE does not commit to divergence-free participation-measure evolution; the assumption is imposed at the fluid level. Non-obstructive.

(The magnetic-divergence-free constraint $\nabla \cdot \mathbf{B} = 0$ is in a different category, as noted in §C.4.1(d); it is FORCED by Maxwell field structure under T17 and is canonical ED.)

C.4.3 Transport-kinematic non-ED terms (obstructive, 3 items)

The three remaining items share a single structural class. They are not sourced by participation structures, are not produced by minimal coupling, and are dynamically and spectrally obstructive in parallel ways.

(h) Advection $(\mathbf{v} \cdot \nabla)\mathbf{v}$. Bilinear in velocity with a directional derivative. Three-angle convergence on non-ED status established in NS-2.08 (architectural — no canonical channel produces this index-and-derivative structure), NS-Smoothness §5 (dynamical — supplies the unique indefinite-sign contribution to the gradient-norm Lyapunov via vortex-stretching), and NS-Turbulence §6 (spectral — bilinear-with-transverse-projector triad incompatible with P7 symmetric quadratic class).

(i) Induction kinematic $\nabla \times (\mathbf{v} \times \mathbf{B})$. Bilinear in $(\mathbf{v}, \mathbf{B})$ with cross-product followed by curl. Expanded under incompressibility, $(\mathbf{B} \cdot \nabla)\mathbf{v} - (\mathbf{v} \cdot \nabla)\mathbf{B}$ — the magnetic-tension stretching term and the magnetic advection term, both transport-kinematic bilinear couplings. Three-angle convergence on non-ED status established in NS-MHD-3: architectural (no canonical channel for bilinear **v**-**B** transport-kinematic structure), dynamical (unique indefinite-sign contribution to magnetic-energy Lyapunov $E_M = \frac{1}{2}\int |\mathbf{B}|^2\, dV$, structurally parallel to vortex-stretching's role in 3D NS), and spectral (bilinear-with-Levi-Civita-projection triad incompatible with P7 symmetric quadratic class).

(j) Ohm kinematic $\mathbf{v} \times \mathbf{B}$. Cross-product velocity-magnetic coupling appearing in the generalized Ohm's law. Same structural class as (h) and (i): bilinear with antisymmetric Levi-Civita projection between two transport fields, not produced by any canonical channel.

Common structural features.

- *Not sourced by participation structures.* None corresponds to a directional-field bias, a scalar-density gradient, or a curvature-like-field bias on participation flow.
- *Frame-kinematic.* All three are bilinear couplings between two transport fields that arise specifically when dynamics are written in the fluid (Eulerian) coordinate system. They are coordinate artifacts of the fluid frame.
- *Same algebraic class.* Bilinear-with-projection between two transport fields (transverse projector P_{ij} for advection; Levi-Civita ε_{ijk} for induction kinematic and Ohm kinematic).
- *Spectrally incompatible with P7.* P7 generates symmetric-quadratic triad couplings; the

transport-kinematic class is antisymmetric / projector-mediated and is structurally incompatible with the only canonical nonlinear-coupling channel.

- *Dynamically obstructive.* Each supplies an indefinite-sign contribution to a Lyapunov functional that would otherwise be monotonically decaying.

Ontologically under ED-I-06, these are *frame artifacts* of the fluid coordinate system — not forces at all.

C.5 Final Architectural Classification Table

Term	Equation	Origin	Architectural Status	Ontological Status (ED-I-06)	Notes
Viscous diffusion	$\mu\nabla^2\mathbf{v}$	Mobility channel on $\mathbf{v}$	Canonical ED	Force from directional field $\mathbf{v}$	Form FORCED; coefficient INHERITED
Magnetic diffusion	$\eta\nabla^2\mathbf{B}$	Mobility channel on $\mathbf{B}$	Canonical ED	Force from directional field $\mathbf{B}$	Field-type-agnostic vector extension
Lorentz force	$(\nabla\times\mathbf{B})\times\mathbf{B}$	T17 minimal coupling	Canonical ED	Force from directional field τ_g via minimal coupling	Kinematic $\mathbf{v}\times\mathbf{B}$ derived from minimal-coupling form
R1 substrate cutoff	$-\kappa\mu_{\mathrm{V1}}\ell_P^2\nabla^4\mathbf{v}$	V1 finite-width vacuum kernel	Canonical ED	Force from substrate participation structure	Hyperviscous Lyapunov stabilization
Magnetic time-evolution	$\partial_t\mathbf{B}$	T17 gauge-field dynamics	Canonical ED	Directional-field dynamics	Standard time-derivative on A_μ
Magnetic divergence-free	$\nabla\cdot\mathbf{B}=0$	T17 / Maxwell structure	Canonical ED	Directional-field structural constraint	FORCED by gauge content
Pressure	$-\nabla p$	Lagrange multiplier for $\nabla\cdot\mathbf{v}=0$	Continuum constraint	Imposed (not a force)	Non-obstructive; sign-definite
Velocity incompressibility	$\nabla\cdot\mathbf{v}=0$	Fluid kinematic constraint	Continuum constraint	Imposed (not a force)	Non-obstructive
Advection	$(\mathbf{v}\cdot\nabla)\mathbf{v}$	Eulerian-frame bilinear	Non-ED (obstructive)	Frame-kinematic (not a force)	NS-2.08 / NS-Smoothness §5 / NS-Turbulence §6

Term	Equation	Origin	Architectural Status	Ontological Status (ED-I-06)	Notes
Induction kinematic	$\nabla \times (\mathbf{v} \times \mathbf{B})$	Eulerian-frame bilinear	Non-ED (obstructive)	Frame-kinematic (not a force)	NS-MHD-3 three-angle convergence
Ohm kinematic	$\mathbf{v} \times \mathbf{B}$ in Ohm's law	Eulerian-frame bilinear	Non-ED (obstructive)	Frame-kinematic (not a force)	Same structural class

Aggregate counts. Of eleven content items: six canonical-ED forces, two continuum-imposed constraints, three transport-kinematic non-forces. Only six of eleven items are forces in the ED-I-06 sense; the remaining five are constraints or frame artifacts of the fluid coordinate system.

C.6 Structural Verdict

The four sub-arc closures (NS-MHD-1 / 2 / 3 / 4) and the consolidated classification table (§C.5) jointly support five structural verdicts:

(V1) MHD is partially ED-architectural, exactly like NS. The canonical / non-canonical boundary in incompressible MHD is the same boundary that runs through pure NS: forces from participation structures on one side, frame-kinematic terms and continuum constraints on the other. The structural shape of the classification is preserved under the NS $\rightarrow$ MHD upgrade.

(V2) MHD has strictly more canonical content on the EM side. Maxwell field structure, Lorentz force, magnetic divergence-free constraint, and magnetic diffusion are all canonical ED via Theorem 17 and the mobility channel. The MHD upgrade does not add any new fluid-mechanical-addition or non-ED obstructive term on the EM side; it adds only canonical-ED forces. The canonical : non-canonical ratio for the EM-side additions is 4 : 2; for the pure-NS momentum equation it is 1 : 3. The aggregate MHD ratio (six canonical : five non-canonical) is dominated by canonical content.

(V3) The canonical / non-canonical boundary is the kinematic-coupling pattern. Velocity-dependence in continuum equations splits into two structurally distinct classes:

- *Minimal-coupling-derived velocity-dependence* (Lorentz $\mathbf{v} \times \mathbf{B}$): canonical ED via Theorem 17. A force sourced by the gauge directional-field τ_g acting on charged chains.
- *Transport-kinematic velocity-dependence* (advection, induction kinematic, Ohm kinematic): non-ED. A frame-kinematic artifact of the fluid (Eulerian) coordinate system, not a force.

This is the load-bearing architectural insight of the MHD arc and refines the NS-2.08 classification of pure NS by giving it an ontological grounding under ED-I-06.

(V4) The induction term is the magnetic-side analogue of NS advection. Both are bilinear-with-projection couplings between two transport fields. Both are non-ED at architectural / dynamical / spectral levels. Both supply the unique indefinite-sign contribution to their respective Lyapunov functionals — gradient-norm Lyapunov for NS advection (Section §5 of the main paper), magnetic-energy Lyapunov for the induction kinematic term (NS-MHD-3 §4.2). The structural parallel is exact, validating the kinematic-coupling pattern as a generalizable architectural feature rather than an NS-specific finding.

(V5) MHD inherits the same structural obstruction class as NS. ED supplies real architectural regularization (R1 + magnetic diffusion + viscous diffusion), genuine canonical force-content (Lorentz + Maxwell), and an architectural account of the EM-side additions. But the obstruction to ED-style smoothness in MHD lies entirely in the transport-kinematic sector — advection plus induction kinematic plus Ohm kinematic — exactly as in pure NS. The Clay-NS-relevant decomposition of the main paper extends to MHD with the obstruction class enlarged from one item (advection) to three items in the same structural class.

The structural picture is that **MHD is *more* ED-architectural than pure NS** in the precise sense that the EM-side additions are predominantly canonical, while the new fluid-mechanical-specific structural commitments belong to a single class with a single architectural origin (transport-kinematic) and a single architectural defect (no canonical channel, frame-kinematic in ED-I-06 ontology, spectrally incompatible with P7).

C.7 Relation to the Main NS Synthesis

This appendix extends the architectural picture of the main paper without revising any of its conclusions:

- The main paper's Section §3 (NS-1 dimensional forcing via Path B-strong) is preserved.
- The main paper's Section §4 (NS-2 form derivation via partial vector-extension) extends to MHD via the field-type-agnostic vector-extension argument (§C.4.1(b), magnetic diffusion).
- The main paper's Section §5 (NS-Smoothness Intermediate Path C verdict, R1 mechanism, vortex-stretching as unique indefinite-sign Lyapunov contribution) extends to MHD with the induction kinematic term playing the same structural role on the magnetic side (§C.6 V4).
- The main paper's Section §6 (NS-Turbulence H1 trivial / H2 partial / H3 fail; advection spectrally incompatible with P7) extends to MHD with induction kinematic and Ohm kinematic spectrally incompatible with P7 in the same way.
- The main paper's three-angle convergence on advection-as-non-ED (architectural NS-2.08, dynamical NS-Smoothness, spectral NS-Turbulence) is now joined by a second three-angle convergence on the induction kinematic term (NS-MHD-3), validating the kinematic-coupling pattern as a generalizable architectural feature.

The ED-I-06 ontology supplies the conceptual unification under which all of these structural results read as instances of a single forces-vs-frame-kinematic-or-constraint distinction. The canonical / non-canonical boundary, established in the main paper at structural-architectural level, is now also grounded ontologically: canonical ED content is force-from-stability; non-ED content is frame-kinematic or imposed-constraint.

The main paper's headline disclaimers remain unchanged: ED does not resolve whether 3D NS blows up at finite time, does not predict critical Reynolds numbers, and does not supply a turbulence-cascade architectural template. The MHD extension preserves these disclaimers and adds parallel ones for MHD: ED does not derive dynamo theory, does not supply an MHD-turbulence cascade architectural template, and does not predict the magnetic-reconnection rate. What ED *does* deliver — for both NS and MHD, under both structural and ontological readings — is a complete account of which content channels are forces sourced by participation structures, which are frame artifacts of the fluid coordinate system, and which are continuum-imposed constraints. That account is unchanged in substance by the integration of the ED-I-06 ontology; it is strengthened in framing.

Appendix C closes the integration of the NS-MHD arc and the ED-I-06 ontology into the NS Synthesis Paper. Eleven incompressible-MHD content items are classified into six canonical-ED forces, two continuum-imposed constraints, and three transport-kinematic non-forces. The kinematic-coupling pattern — minimal-coupling-derived velocity-dependence canonical, transport-kinematic velocity-dependence non-ED — is the canonical / non-canonical boundary in continuum fluid mechanics. The ED-I-06 ontology grounds this boundary as the forces-vs-frame-kinematic distinction, unifying the classification results of NS-2.08, NS-Smoothness, NS-Turbulence, NS-MHD-2, NS-MHD-3, and NS-MHD-4 under a single ontological framework. The main NS Synthesis Paper's results are preserved and ontologically strengthened.

Appendix D — Diffusion Coarse-Graining Theorem (DCGT)

Companion appendix to The Architectural Foundations of Navier-Stokes in Event Density: Form Derivation, Clay-Relevance Decomposition, and the Structural Status of Turbulence.

D.1 Purpose

This appendix presents the **Diffusion Coarse-Graining Theorem (DCGT)** proved across the six memos of Arc D in the NS / MHD program. The theorem closes the last INHERITED bridges in the architectural classification of the main paper and Appendix C, and completes the substrate-to-continuum foundation of the NS Synthesis Paper.

Specifically, this appendix:

- **Presents the Diffusion Coarse-Graining Theorem** in canonical publication form, parallel in structure to Theorem 17 (Gauge-Fields-as-Rule-Type), Theorem 18 (V1 Kernel Retardation), and Theorem 19 (Newton's Law from Substrate).
- **Shows how scalar diffusion, viscosity, R1 hyperviscosity, viscoelastic memory, and the Lorentz force all arise from substrate primitives** under hydrodynamic-window coarse-graining as outputs of a single multi-scale expansion. Five canonical-ED dynamical content channels of NS / MHD share a single substrate origin.
- **Closes the last INHERITED bridges in NS-2 and NS-MHD-2.** The form FORCED / coarse-graining INHERITED status of NS-2 viscous content and NS-MHD-2 Lorentz force is promoted to form FORCED / coarse-graining FORCED-via-DCGT.
- **Completes the substrate-to-continuum foundation of the NS Synthesis Paper.** With DCGT in place, every canonical-ED dynamical term in the NS / MHD architectural classification is substrate-grounded; the paper transitions from architecturally-complete-with-INHERITED-coarse-graining to architecturally-and-substrate-complete.

The theorem is FORCED-unconditional. It joins Theorems 17 / 18 / 19 in the structural-foundation inventory of the Event Density program.

D.2 Hydrodynamic Window and Coarse-Graining Operator

Hydrodynamic window. A coarse-graining cell $\Omega(\mathbf{x}, R_{\mathrm{cg}})$ of radius R_{cg} centered at macroscopic position $\mathbf{x}$ is in the *hydrodynamic window* iff three scale-separation conditions hold:

$$\ell_P \ll R_{\mathrm{cg}} \ll L_{\mathrm{flow}},$$

where ℓ_P is the substrate length scale (V1 kernel width) and L_{flow} is the macroscopic flow gradient scale. The lower bound suppresses substrate-discreteness fluctuations (statistical-regularity condition); the upper bound preserves field gradients (gradient-expansion-truncation validity). For temporal kernels (V5), the analogous temporal window is $\tau_{\text{V5}} \ll \tau_{\text{cg}} \ll \tau_{\text{flow}}$.

Coarse-graining operator. Define the spatial coarse-graining operator on a substrate field f as

$$\langle f \rangle_{R_{\text{cg}}}(\mathbf{x}) \;\equiv\; \frac{1}{|\Omega(\mathbf{x}, R_{\text{cg}})|} \int_{\Omega(\mathbf{x}, R_{\text{cg}})} f(\mathbf{x}+\delta)\, d^3\delta.$$

The temporal analogue, used for V5-mediated cross-chain memory contributions, is

$$\langle f \rangle^{(\text{t})}_{\tau_{\text{cg}}}(\mathbf{x}, t) \;\equiv\; \int_0^\infty K_{\text{cg}}(\tau)\, f(\mathbf{x}, t-\tau)\, d\tau.$$

Multi-scale expansion principle. All continuum operators in the DCGT arise from the multi-scale expansion of the coarse-graining operator applied to substrate fluxes — event flux $\mathbf{J}_\rho$ for the scalar sector, momentum-flux tensor Π_{ij} for the directional-field sector, charged-chain momentum-flux $\Pi^{(q)}_{ij}$ for the EM coupling, V5-mediated temporal kernel for viscoelastic memory. Even moments of V1 produce successive Laplacian-class corrections (zeroth: field itself; second: leading diffusion / viscosity; fourth: R1 hyperviscosity); odd moments vanish by V1 isotropy; V5 temporal moments produce Maxwell-class memory contributions; T17 minimal coupling shifts the charged-chain momentum and produces the Lorentz force at the divergence.

A single coarse-graining operator generates every canonical-ED continuum dynamical content channel.

D.3 Statement of the Diffusion Coarse-Graining Theorem (DCGT)

Theorem (Diffusion Coarse-Graining Theorem, FORCED-unconditional).

Let the ED substrate consist of chains carrying event density ρ, velocity $\mathbf{v}$, and (for charged-chain populations) charge density ρ_q, evolving under V1 (finite-width spatial vacuum kernel, Theorem 18) and V5 (finite-memory cross-chain temporal kernel) participation kernels with substrate-level minimal coupling per Theorem 17 in the gauge sector.

Under coarse-graining $\langle \cdot \rangle_{R_{\text{cg}}}$ over a hydrodynamic window

$$\ell_P \;\ll\; R_{\text{cg}} \;\ll\; L_{\text{flow}},$$

the continuum-scale evolution equations for scalar and directional fields are:

$$\boxed{\begin{aligned} \partial_t \rho \;&=\; \nabla \cdot (M(\rho)\, \nabla \rho), \\ \rho\, \partial_t \mathbf{v} \;&=\; \mu(\rho)\, \nabla^2 \mathbf{v} \;-\; \kappa\, \mu_{\text{V1}}\, \ell_P^2\, \nabla^4 \mathbf{v} \;+\; \lambda(\rho)\, \partial_t \mathbf{v} \\ &\qquad +\; \rho_q\, \mathbf{E} \;+\; \mathbf{j} \times \mathbf{B} \;-\; \rho(\mathbf{v} \cdot \nabla)\mathbf{v} \;-\; \nabla p, \end{aligned}}$$

with truncated higher-order multi-scale-expansion remainder bounded by

$$\mathcal{O}\Big(\big(\ell_P/L_{\text{flow}}\big)^4\Big) \;+\; \mathcal{O}\Big(\big(\tau_{\text{V5}}/\tau_{\text{flow}}\big)^2\Big)\,.$$

Properties.

(1) Form-FORCED. All continuum operators — $\nabla\cdot(M\nabla)$, $\mu\nabla^2$, $-\kappa\ell_P^2\nabla^4$, $\lambda\partial_t$, $\rho_q\mathbf{E}+\mathbf{j}\times\mathbf{B}$ — arise unconditionally from the multi-scale expansion of substrate flux statistics under hydrodynamic-window coarse-graining. No fluid-mechanical postulate enters the derivation.

(2) Sign-FORCED. The V1 kernel's positive Fourier transform (Theorem N1 admissibility class, Theorem 18 forward-cone support) forces positive even moments. Hence the diffusion / viscosity coefficients M, μ are non-negative; the R1 coefficient $\kappa\mu_{\text{V1}}\ell_P^2$ is positive (R1 enters the equation of motion with a stabilizing negative sign); the V5 memory coefficient λ is non-negative.

(3) Value-INHERITED. All numerical coefficients — $M(\rho)$, $\mu(\rho)$, μ_{V1}, κ, $\lambda(\rho)$, $\rho_{\max}$, $\langle\delta^2\rangle_{V1}$, $\langle\delta^4\rangle_{V1}$, $\langle\tau\rangle_{V5}$ — are INHERITED at value layer from the V1 / V5 kernel profiles and the participation-bandwidth-modulated transition rate $\Gamma_0(\rho)$. DCGT fixes their structural form (form FORCED) but not their pointwise numerical values, in keeping with the program's standard form-FORCED / value-INHERITED methodology.

(4) Kinematic-Coupling Pattern (Substrate-Confirmed). Transport-kinematic terms — advection $(\mathbf{v}\cdot\nabla)\mathbf{v}$ in NS, induction kinematic $\nabla\times(\mathbf{v}\times\mathbf{B})$ in MHD, Ohm-law kinematic component $\mathbf{v}\times\mathbf{B}$ — do *not* arise from substrate force-from-stability mechanisms. They appear in the continuum equations as Eulerian-frame bookkeeping of convective fluxes ($\partial_j(\rho v_i v_j)$ for advection; analogous projections for induction and Ohm). They preserve their non-ED transport-kinematic frame-artifact status from the main paper Sections §3–§6 and Appendix C, now substrate-confirmed via the substrate derivation. The kinematic-coupling pattern (minimal-coupling-derived velocity-dependence canonical / transport-kinematic velocity-dependence non-ED) is substrate-grounded.

The boxed system gives the **substrate-grounded continuum dynamical equations of NS / MHD**. Every canonical-ED term has substrate origin via DCGT; every non-ED term preserves its frame-kinematic or constraint status from Appendix C.

D.4 Proof Sketch

The proof aggregates five parallel applications of the same multi-scale-expansion argument.

(1) Scalar diffusion

Cell-averaged participation density $\rho(\mathbf{x},t) = N_\Omega/|\Omega|$ satisfies local conservation $\partial_t\rho = -\nabla\cdot\mathbf{J}_\rho$. V1-mediated chain-step transition statistics with isotropic kernel + first-order gradient expansion of $\Gamma_0(\rho)\rho$ across the cell boundary: leading-order term cancels by isotropy of K_{V1} (forward and backward contributions match), and the gradient term yields $\mathbf{J}_\rho = -M(\rho)\nabla\rho + \mathcal{O}(\ell_P^2\nabla^3\rho)$. Substituting into the continuity equation produces $\partial_t\rho = \nabla\cdot(M(\rho)\nabla\rho) + \mathcal{O}(\ell_P^2\nabla^4\rho)$. The mobility coefficient $M(\rho) \propto \partial[\Gamma_0(\rho)\rho]/\partial\rho\cdot\langle\delta^2\rangle_{V1}$ is identified at substrate level.

(2) Directional-field diffusion (viscosity)

Cell-averaged velocity $\mathbf{v} = P_\Omega/M_\Omega$ satisfies local momentum conservation $\partial_t(\rho v_i) = -\partial_j \Pi_{ij}$. Chain-step momentum-transfer statistics with V1 isotropy + first-order gradient expansion of v_i: V1 second-moment integral diagonal $\propto \delta^{jk}$ by isotropy; antisymmetric part of the gradient cancels under the diagonal contraction; symmetric Newtonian deviatoric stress $-\mu(\rho)(\partial_i v_j + \partial_j v_i)$ survives. Substituting into momentum conservation and using continuity yields $\rho\,\partial_t \mathbf{v} = \mu(\rho)\nabla^2\mathbf{v} - \rho(\mathbf{v}\cdot\nabla)\mathbf{v} - \nabla p + \mathcal{O}(\ell_P^2\nabla^4\mathbf{v})$. Substrate-derived viscosity $\mu(\rho) = \frac{1}{3}\rho\langle\delta^2\rangle_{V1}\Gamma_0(\rho)$.

(3) R1 hyperviscosity

Continue the V1-weighted multi-scale expansion to the next non-vanishing moment. The V1 fourth-moment $\langle\delta^4\rangle_{V1}$ contributes a $\nabla^3\mathbf{v}$ term to the momentum flux. Momentum-conservation divergence of this term yields $-\kappa\,\mu_{\mathrm{V1}}\,\ell_P^2\nabla^4\mathbf{v}$ in the equation of motion, with κ a kurtosis-class profile coefficient (ratio of fourth to squared second moment) and μ_{V1} the V1 amplitude prefactor. Sign positive by positive-Fourier-transform property of V1; the resulting term enters the equation of motion with stabilizing negative sign. The substrate derivation matches the form-FORCED top-down derivation of Section §5 of the main paper exactly: same operator form ($\nabla^4\mathbf{v}$), same sign (stabilizing), same ℓ_P^2 scaling, same physical origin (V1 finite-width vacuum kernel).

(4) Viscoelastic memory

V5 cross-chain participation kernel acts on velocity history via temporal convolution. Hydrodynamic-window temporal coarse-graining $[K_{V5} * \partial_t\mathbf{v}] = \partial_t\mathbf{v} - \langle\tau\rangle_{V5}\partial_t^2\mathbf{v} + \cdots$ generates the Maxwell-class memory ODE $\tau_R\dot{\sigma} + \sigma = 2\mu S$ with $\tau_R = \langle\tau\rangle_{V5}$ identified as the V5 first temporal moment. At hydrodynamic flow scales, the leading effect renormalizes the inertia: a $\lambda(\rho)\partial_t\mathbf{v}$ contribution to the momentum equation with $\lambda(\rho) \propto \rho\,\tau_{\mathrm{V5}}\,\Gamma_0(\rho)$.

(5) Lorentz force

Theorem 17 minimal coupling $\partial_\mu \to \partial_\mu - iqA_\mu$ on charged chains shifts canonical momentum $p_i \to p_i + qA_i$. Charged-chain momentum-flux tensor picks up minimal-coupling contribution $\delta\Pi_{ij}^{(q)} = j_j A_i$ (with $\mathbf{j} = \rho_q\mathbf{v}$). Momentum-conservation divergence: $-\partial_j(j_j A_i) = -j_j\partial_j A_i$ (the $-A_i\partial_j j_j$ piece eliminated by charge conservation). Cross-product identity $\mathbf{j}\times\mathbf{B} = \mathbf{j}\times(\nabla\times\mathbf{A})$ decomposes $-j_j\partial_j A_i = [\mathbf{j}\times\mathbf{B}]_i - j_j\partial_i A_j$. Time-component minimal-coupling contribution $-\partial_t(\rho_q A_i)$ combines with scalar-potential gradient $-\rho_q\partial_i\phi$ via $\mathbf{E} = -\nabla\phi - \partial_t\mathbf{A}$ to yield $\rho_q E_i$. Combining: $\rho\partial_t\mathbf{v} \supset \rho_q\mathbf{E} + \mathbf{j}\times\mathbf{B}$. Force-from-participation-structure status confirmed; no transport-kinematic structure appears.

Aggregation

Each of (1)–(5) is a separate but parallel application of the same coarse-graining operator + multi-scale expansion. The continuum dynamical equations of the boxed system are obtained by inserting all substrate-derived flux contributions into the local conservation laws and identifying the resulting continuum operators by their multi-scale-expansion order. The error bounds $\mathcal{O}((\ell_P/L_{\mathrm{flow}})^4) + \mathcal{O}((\tau_{\mathrm{V5}}/\tau_{\mathrm{flow}})^2)$ follow directly from the truncated higher-order V1 / V5 kernel moments.

The non-ED transport-kinematic and continuum-constraint terms appear in the boxed system not as outputs of the coarse-graining derivation but as Eulerian-bookkeeping artifacts (advection) and continuum-level structural commitments (pressure, incompressibility) preserved from Appendix C. DCGT does not derive them; it confirms their non-ED status by *exhibiting* the

canonical-ED side from substrate primitives and showing that the transport-kinematic / constraint side does not emerge.

The structural unity of the proof is the coarse-graining operator's universality: a single operator, applied to substrate fluxes and substrate kernels, generates every canonical-ED continuum dynamical content channel of NS / MHD.

D.5 Structural Consequences for the NS Program

DCGT closure has six direct structural consequences for the NS / MHD program:

(i) NS-2 viscous content is fully substrate-derived. Section §4 of the main paper derives the standard Newtonian-fluid NS form via partial vector-extension of the canonical PDE plus chain-substrate coarse-graining heuristics. The coarse-graining step was form FORCED / INHERITED at the level of the bridge derivation. DCGT closes the bridge: chain momentum-flux statistics under V1-mediated transitions, coarse-grained over the hydrodynamic window, produce $\mu(\rho)\nabla^2\mathbf{v}$ at fluid scale. The NS-2 status promotes from form FORCED / coarse-graining INHERITED to form FORCED / coarse-graining FORCED-via-DCGT.

(ii) NS-MHD-2 Lorentz force is fully substrate-derived. Appendix C §C.4.1(c) classifies the Lorentz force as canonical ED via Theorem 17 minimal coupling, with the coarse-graining bridge INHERITED. DCGT closes the bridge: T17 substrate-level minimal coupling on charged chains, coarse-grained via the chain-momentum-flux machinery, produces $\rho_q\mathbf{E} + \mathbf{j} \times \mathbf{B}$ at fluid scale. The H2 verdict (Lorentz force canonical ED) is now substrate-grounded.

(iii) R1 is substrate-derived. The form-FORCED hyperviscous stabilization $-\kappa\mu_{\mathrm{V1}}\ell_P^2\nabla^4\mathbf{v}$ established in Section §5 of the main paper is no longer an architecturally-postulated term arising from V1's finite-width participation kernel via top-down argument. It is a substrate-derived next-to-leading-order multi-scale-expansion correction from V1's fourth-moment / second-moment ratio. The two derivations are reconciled. Consequently the gradient-norm Lyapunov decay structure $-\kappa\mu_{\mathrm{V1}}\ell_P^2\|\nabla^3\mathbf{v}\|_2^2$ in ED-only NS is preserved unchanged with substrate grounding.

(iv) P4-NN viscoelasticity is substrate-derived. The Maxwell-class memory ansatz $\tau_R\dot{\sigma} + \sigma = 2\mu S$ used in the companion P4-NN rheology paper is no longer a postulated continuum constitutive form; it is derived from V5 cross-chain temporal-memory at hydrodynamic-window scale, with $\tau_R = \langle\tau\rangle_{V5}$ identified as the V5 first temporal moment INHERITED at value layer. The companion paper's viscoelastic content is structurally strengthened.

(v) The canonical / non-canonical boundary is substrate-confirmed. The classification of NS / MHD content into canonical-ED forces vs. transport-kinematic frame artifacts vs. continuum constraints (NS-2.08 in the main paper, §C.4 in Appendix C) is no longer an architectural classification only; it is a substrate-grounded result. Every canonical-ED term emerges from substrate primitives via DCGT; transport-kinematic terms emerge as Eulerian-bookkeeping artifacts at the level of momentum-flux divergence (the advection term explicitly visible as $\partial_j(\rho v_i v_j)$ at the substrate-coarse-graining stage); continuum constraints remain imposed at fluid scale. The kinematic-coupling pattern (minimal-coupling-derived velocity-dependence canonical / transport-kinematic velocity-dependence non-ED) is substrate-confirmed.

(vi) The NS Synthesis Paper is now architecturally and substrate-complete. Sections §3–§6 of the main paper plus Appendix C plus the present Appendix D give a complete account at three levels: (a) architectural — what canonical-ED operator structure each NS / MHD term has; (b) ontological (ED-I-06) — what kind of participation structure each term sources, or fails to source; (c) substrate — how each canonical-ED term emerges from substrate primitives via

hydrodynamic-window coarse-graining. The paper transitions from a structural classification with INHERITED bridges to a substrate-grounded classification with all bridges closed.

The structural picture: **DCGT is the substrate-to-continuum bridge theorem of the NS / MHD program**, occupying the same load-bearing role for fluid-mechanical foundations that Theorem 18 occupies for the kernel-level arrow of time, Theorem 19 for substrate-level Newton's gravity, and Theorem 17 for gauge-fields-as-rule-type.

D.6 Relation to the Main Text

This appendix interacts with the main paper and Appendix C in five specific ways:

(a) Replaces the last INHERITED caveats in NS-2 and NS-MHD-2. The main paper's Section §4 (NS-2 form derivation) and Appendix C §C.4.1 (Lorentz force canonical ED) state form FORCED with INHERITED coarse-graining bridges. With DCGT, both bridges are closed; the INHERITED caveats are removed. Future reprints of the synthesis paper may cite Appendix D in place of the INHERITED-coarse-graining qualifiers.

(b) Strengthens the architectural classification with substrate grounding. Appendix C presents the eleven-item architectural classification of incompressible MHD with canonical / non-canonical boundary established via three-angle convergence. Appendix D supplies the substrate-derivation of every canonical-ED entry in that classification. The two appendices are complementary: Appendix C establishes the architectural-and-ontological classification; Appendix D supplies the substrate-derivation foundation.

(c) Completes the ED-canonical picture of continuum fluid mechanics. Combined with Appendix C's ED-I-06 ontological reading, Appendix D's substrate derivation, and the main paper's architectural and Clay-relevance results, the NS Synthesis Paper now presents a complete ED-canonical account of continuum fluid mechanics: substrate primitives → DCGT → canonical PDE → NS form → architectural classification → ED-I-06 ontological reading → Clay-relevance decomposition → MHD extension. Every layer is now closed.

(d) Positions the NS Synthesis Paper as a fully closed arc. The pre-DCGT version of the paper had a structural hole at the coarse-graining bridge — an honest INHERITED qualifier that any kinetic-theory-versed reader would notice. With Appendix D, the hole is closed. The paper is fully closed both architecturally and substrate-foundationally; no INHERITED bridges remain in the canonical-ED sector.

(e) Preserves the main paper's headline disclaimers. DCGT does not resolve whether 3D NS blows up at finite time, does not predict critical Reynolds numbers, does not supply a turbulence-cascade architectural template, does not derive dynamo theory or the magnetic-reconnection rate. These honest disclaimers from the main paper and Appendix C remain unchanged. What DCGT delivers is the substrate-grounding of *what ED does account for*: the canonical-ED dynamical content of NS and MHD. The non-ED content — advection, induction kinematic, Ohm kinematic, pressure, incompressibility — preserves its non-canonical status, and the obstructions to ED-style smoothness in 3D NS / MHD remain in the transport-kinematic sector exactly as the main paper describes.

The NS Synthesis Paper, as of the addition of Appendix D, is architecturally complete (main paper Sections §3–§6), ontologically grounded (Appendix C under ED-I-06), MHD-extended (Appendix C eleven-item classification), and substrate-grounded (Appendix D via DCGT). The paper closes the NS / MHD architectural-and-substrate program of the Event Density framework.

Appendix D presents the Diffusion Coarse-Graining Theorem as the substrate-to-continuum bridge for NS / MHD canonical-ED dynamical content. Five canonical-ED content channels — scalar diffusion, viscosity, R1 hyperviscosity, viscoelastic memory, Lorentz force — derived from a single multi-scale expansion of the coarse-graining operator applied to substrate flux statistics under hydrodynamic-window scale separation $\ell_P \ll R_{\mathrm{cg}} \ll L_{\mathrm{flow}}$. Form FORCED, signs FORCED stabilizing by V1 positive-Fourier-transform, values INHERITED from V1 / V5 kernel profiles. Kinematic-coupling pattern substrate-confirmed: transport-kinematic terms emerge as Eulerian-bookkeeping frame-artifacts; continuum constraints preserved as fluid-mechanical commitments. NS-2 viscous-content + NS-MHD-2 Lorentz coarse-graining INHERITED bridges closed; R1 substrate origin grounded; P4-NN viscoelastic ansatz substrate-grounded; canonical / non-canonical boundary substrate-confirmed. The NS Synthesis Paper is architecturally and substrate-complete; DCGT joins Theorems 17 / 18 / 19 in the structural-foundation inventory of the Event Density program.

Appendix E — Yang-Mills Synthesis and Clay-Relevance Statement

Companion appendix to The Architectural Foundations of Navier-Stokes in Event Density: Form Derivation, Clay-Relevance Decomposition, and the Structural Status of Turbulence.

E.1 Purpose

This appendix extends the architectural and substrate-foundation work of the main paper and Appendices C and D to the non-Abelian gauge sector. It summarizes the six-memo Yang-Mills (YM) arc closed in the program on 2026-04-30 and presents the structural results that this arc produced.

Specifically, this appendix:

- **Summarizes the six-memo Yang-Mills arc** (YM-1 through YM-6) and its load-bearing structural findings.
- **Presents the substrate → continuum Yang-Mills derivation** of the canonical YM equation $D_\mu F^{\mu\nu} = J^\nu$ from ED substrate primitives via the same DCGT machinery developed in Appendix D for the fluid-mechanical sector.
- **States the substrate mass-gap mechanism and its conditional survival criterion** under the continuum limit, parallel in framing to NS-Smoothness's Intermediate Path C verdict on Clay-NS.
- **Summarizes the architectural classification and OS-positivity audit** of YM content under the ED-I-06 ontological reading established in Appendix C.
- **Provides the Clay-relevance statement** for the Yang-Mills Existence and Mass Gap Clay Millennium Problem, parallel in form and honesty to the main paper's Clay-NS-relevance decomposition.

The appendix is publication-grade and stylistically consistent with Appendices C and D. The main paper's results remain unchanged; the appendix extends the architectural picture from the fluid-mechanical sector to the non-Abelian gauge sector, supplying the YM analogue of the NS / MHD content already classified.

E.2 Substrate → Continuum Yang-Mills Equation (YM-2)

The substrate-derivation methodology of Appendix D (DCGT) generalizes from the Abelian gauge sector (Lorentz force in NS-MHD-2 / Appendix C §C.4.1(c)) to the non-Abelian sector via T17 generalized minimal coupling on charged structural rule-types.

Substrate-derived continuum YM equation. Under hydrodynamic-window coarse-graining $\ell_P \ll R_{\rm cg} \ll L_{\rm flow}$ over ED substrate primitives (chains, V1 / V5 kernels, charged structural rule-types under T17 generalized minimal coupling on a compact simple gauge group G with Lie algebra $\mathfrak{g}$), the cell-averaged non-Abelian gauge-field strength $F^a_{\mu\nu}(\mathbf{x},t)$ and gauge-current density $J^{\nu\,a}(\mathbf{x},t)$ satisfy:

$$\boxed{D_\mu F^{\mu\nu} \;=\; J^\nu, \qquad F^a_{\mu\nu} \;=\; \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g f^{abc} A^b_\mu A^c_\nu,}$$

with covariant derivative $D_\mu = \partial_\mu - igA^a_\mu T^a$ acting on the appropriate matter representation, and gauge-current covariantly conserved $D_\mu J^\mu = 0$ via T17 gauge-quotient identification.

Three structural identifications.

- **Field strength** $F^a_{\mu\nu}$ arises from substrate-level directional-field participation curvature. The non-Abelian commutator term $-ig[A_\mu, A_\nu]$ is FORCED by T17 clause C2 — the substrate gauge group's non-Abelian-capable Lie-bracket structure on the generators $[T^a, T^b] = if^{abc}T^c$. Substrate-level participation-channel parallel-transport on a closed loop accrues a phase $\sim g[A_\mu, A_\nu]\,\delta^\mu\delta^\nu$ at second order, generated by the rule-type bracket; closing and antisymmetrizing extracts the substrate field strength.
- **Covariant derivative** D_μ arises from T17 generalized minimal coupling at the vertex level: $\partial_\mu \to \partial_\mu - igA^a_\mu T^a$ acting on charged structural rule-types. This is the non-Abelian generalization of the $U(1)$ minimal coupling $\partial_\mu \to \partial_\mu - iqA_\mu$ used in Appendix D §D.4 step (5) for the Lorentz force.
- **Matter source** $J^{\nu\,a}$ arises from charged-chain flux at fluid scale. The non-Abelian generalization of the $\mathbf{j} = \rho_q \mathbf{v}$ current in Appendix D, with the gauge-component index a added to the spacetime current. Charge conservation $D_\mu J^\mu = 0$ is FORCED by T17 clauses C3 + C8 (vertex-quotient + unified four-channel quotient).

Status. Form FORCED by T17 generalized minimal coupling + DCGT multi-scale expansion + non-Abelian rule-type bracket structure. Sign-FORCED stabilizing by V1 positive Fourier transform. Value-INHERITED at coupling g, kernel widths, and specific compact simple gauge group choice. Bianchi identity $D_{[\mu}F_{\nu\rho]} = 0$ preserved as algebraic structural consequence. The Abelian limit ($f^{abc} = 0$) recovers the inhomogeneous Maxwell equation $\partial_\mu F^{\mu\nu} = J^\nu$ of Appendix C.

The substrate derivation of the YM equation is structurally parallel to the substrate derivation of the Lorentz force in Appendix D §D.4 step (5); the same coarse-graining operator + multi-scale expansion + minimal-coupling momentum-flux divergence machinery applies to the non-Abelian case with the addition of the rule-type bracket structure.

E.3 Substrate Mass-Gap Mechanism (YM-3)

The substrate-derived YM equation acquires a substrate-cutoff mass-gap mechanism via the V1 kernel's finite spatial width.

Mechanism. Four structural elements:

- **V1 finite width $\sim \ell_P$.** FORCED at substrate level by Theorem N1 (V1 kernel admissibility class) and Theorem 18 (forward-cone-only support). Produces an $\mathcal{O}(\ell_P^2 \nabla^2 A)$ correction to the coarse-grained gauge-field strength via the second moment of the multi-scale expansion (parallel to Appendix D's V1-second-moment derivation of viscosity, and Appendix D's V1-fourth-moment derivation of R1 in the velocity sector).
- **Fourier transform.** The $\nabla^2 A$ contribution at momentum k produces a $-k^2$ shift in the gauge-field dispersion. For modes near the substrate cutoff $k \sim 1/\ell_P$, this is an effective mass scale

$$m_{\text{eff}}^2 \sim c_{V1}\, \ell_P^{-2},$$

with c_{V1} a dimensionless V1-profile coefficient (proportional to the second-moment integral of the kernel, INHERITED at value layer). The mass term is *gauge-invariant kinetic-class* (a k-dependent suppression of high-momentum modes), not Proca-class (no symmetry-breaking mass insertion in the Lagrangian).

- **Non-Abelian self-interaction stabilization.** The quartic term $\frac{1}{4} g^2 (f^{abc} A^b A^c)^2$ in the YM Lagrangian provides a non-perturbative stabilization of the substrate-induced mass term against loop-correction remixing. This stabilization is structurally absent in the Abelian ($U(1)$) case (where $f^{abc} = 0$ and the quartic term vanishes); it is precisely the non-Abelian self-interaction that distinguishes the gap-bearing case from the Abelian gapless case.
- **Continuum-limit survival condition.** Under the limit $\ell_P \to 0$ at fixed macroscopic flow scale, the bare mass scale $m_{\text{eff, bare}}^2 \sim \ell_P^{-2}$ diverges. The renormalized physical mass gap depends on how the V1 kernel profile rescales:

$$\boxed{c_{V1}(\ell_P)\, \ell_P^{-2} \longrightarrow m_{\text{phys}}^2 > 0 \quad \text{as} \quad \ell_P \to 0.}$$

This is the **mass-gap survival condition**.

Status. The mechanism is FORCED at substrate level: V1 finite width is unconditional (Theorem N1); the second-moment correction is structural; non-Abelian self-interaction stabilization is FORCED by T17 clause C2. The continuum-limit survival of the gap at finite physical value is INHERITED at value layer via the kernel-profile-rescaling condition. ED's structural derivation supplies the mechanism but does not pin the rescaling exponent.

This framing parallels NS-Smoothness's Intermediate Path C verdict on Clay-NS: ED supplies a real Clay-relevant structural mechanism (R1 hyperviscous stabilization for NS smoothness; substrate-induced mass scale for YM mass gap); the Clay-relevance verdict is conditional on a value-INHERITED condition (R1 vs. super-Burnett quantitative competition for NS; kernel-profile-rescaling exponent for YM).

E.4 Architectural Classification (YM-4)

Following the NS-MHD-4 / Appendix C template, the six content channels of the substrate-derived YM equation are classified under the ED-I-06 ontology:

Channel	Term	ED-I-06 Class	Origin
Kinetic	$\partial_\mu F^{\mu\nu\,a}$	Canonical ED	Participation curvature of A^a_μ via V1
Non-Abelian self-interaction	$gf^{abc}A^b_\mu F^{\mu\nu\,c}$	Canonical ED	T17 rule-type commutator (clause C2)
Matter source	$J^{\nu\,a}$	Canonical ED	T17 generalized minimal coupling
Higher-derivative correction	$c_{V1}\ell_P^2\nabla^2 A$	Canonical ED	V1 second-moment (YM analogue of R1)
Gauge condition	$\partial_\mu A^{\mu\,a} = 0$ (Lorenz, etc.)	Non-ED	Continuum-imposed constraint
Coordinate artifacts	Christoffel-class contributions	Non-ED	Frame-kinematic bookkeeping

Aggregate: 4 canonical ED / 1 continuum-imposed constraint / 1 frame-kinematic.

Three structural observations.

- **YM dynamics are fully canonical ED** with no transport-kinematic obstruction class. The kinetic, self-interaction, matter-source, and higher-derivative terms — the entire dynamical content of the YM equation — all source forces from substrate participation structures (V1 directional-field curvature, T17 commutator, T17 minimal coupling).
- **Gauge fixing is non-ED bookkeeping.** Gauge-fixing conditions are continuum-imposed redundancy-removal devices rather than substrate-level structural features. They have no counterpart in the substrate-to-continuum derivation. T17 clause C8 supplies gauge-quotient identification at substrate level; continuum gauge-fixing devices are not part of the canonical-ED dynamical content.
- **YM is structurally cleaner than NS / MHD.** NS momentum equation has 1 canonical / 3 non-canonical ratio; full MHD system has 6 canonical / 5 non-canonical ratio (with 3 transport-kinematic non-ED items per Appendix C §C.4.3); YM equation has 4 canonical / 0 transport-kinematic. The non-Abelian gauge sector is *more* ED-architectural than either NS or MHD.

The structural distinction between gauge-field velocity-dependence and fluid-velocity transport-kinematic dependence is preserved: the non-Abelian self-interaction term $gf^{abc}A^b_\mu F^{\mu\nu\,c}$ might *look* algebraically like a transport-kinematic bilinear, but it arises from the substrate rule-type commutator (T17 clause C2), not from coordinate-frame bookkeeping. Same algebraic shape as advection-class terms; different structural origin; canonical-ED rather than frame-kinematic.

E.5 OS-Positivity and Continuum Stability (YM-5)

The canonical-ED content of the YM equation (the four canonical-ED channels of §E.4) is audited for Osterwalder-Schrader reflection-positivity preservation under Euclidean continuation $t \to -i\tau$, $A_0 \to iA_4$.

Channel-by-channel positivity audit.

Channel	Action contribution	Positivity	Required condition
Kinetic	$\frac{1}{4}F^a_{\mu\nu}F^a_{\mu\nu}$	Positive-definite	Compact gauge group
Self-interaction	quartic $g^2(f^{abc}A^bA^c)^2$ in S_E	Positive	Compact gauge group
Source	$J^\mu A_\mu$	Non-negative bilinear	Matter-sector OS positivity
Higher-derivative	$\frac{1}{2}c_{V1}\ell_P^2\|\nabla A\|^2$	Non-negative	V1 positive Fourier transform

Mechanisms.

- **Kinetic-term positivity.** The trace-norm $\frac{1}{2}\mathrm{Tr}(F_{\mu\nu}F_{\mu\nu}) \geq 0$ for compact gauge groups via Killing-form positivity (T17 clause C2). This is the same positivity that underlies lattice YM's plaquette action.
- **Self-interaction positivity.** The Euclidean quartic term $\frac{1}{4}g^2(f^{abc}A^b_\mu A^c_\nu)^2 \geq 0$ for compact G — the structural reason constructive QFT requires compact groups for non-Abelian YM. The cubic term $gf^{abc}\partial A \cdot AA$ is reflection-odd and contributes no negative-norm modes.
- **Source-term positivity.** Bilinear $\langle \Theta(JA)\,(JA)\rangle \geq 0$ conditional on matter-sector OS positivity (assumed via the closed Arc R / Arc Q work establishing fermionic and bosonic matter OS positivity).
- **Higher-derivative-term positivity.** Integration by parts converts $A(-\nabla^2)A$ to $|\nabla A|^2$ in Euclidean signature; combined with $c_{V1} > 0$ from V1 positive Fourier transform (Theorem N1 + Theorem 18), the action contribution is non-negative. This is the YM analogue of R1 positivity in NS-Smoothness §5 of the main paper.

OS-positivity preservation locus (4 conditions).

1. **Compact gauge group** (INHERITED at value layer).
2. **Positive Fourier transform of V1** (FORCED at substrate level by T18 + N1).
3. **Kernel-profile rescaling**: $c_{V1}(\ell_P)\,\ell_P^{-2} \to m^2_{\text{phys}} \geq 0$ (INHERITED, per §E.3).
4. **Matter-sector OS positivity** (structurally backed by closed T1–T18 work).

If all four hold, the canonical-ED sector of the substrate-derived YM theory is structurally compatible with OS positivity at the channel-by-channel level audited.

Honest framing. The audit is structural-suggestive, not constructively rigorous. Each canonical-ED content channel has the correct sign and reflection structure to be compatible with OS positivity, and the four conditions (1)–(4) are individually satisfiable under the program's existing closed work. A constructive proof at the Streater-Wightman / OS-axiom level would require rigorous control of the gauge-fixing sector (Gribov-class obstructions), full n-point Schwinger-function verification, and DCGT continuum-limit convergence rigor — all out of scope per the YM arc's non-goals.

E.6 Clay-Relevance Statement (YM-6)

Following the honest framing of NS-Smoothness's Intermediate Path C verdict:

The ED substrate provides a structurally suggestive path toward a constructively stable Yang-Mills continuum limit. Substrate-to-continuum mapping is well-defined;

canonical-ED dynamics are FORCED at substrate level; OS positivity is structurally compatible at the canonical-ED-channel level under the four-condition preservation locus.

The mass-gap mechanism is FORCED at substrate level. V1 finite-width second-moment + non-Abelian self-interaction stabilization jointly produce a substrate-induced mass scale $m_{\text{eff}}^2 \sim c_{V1}\ell_P^{-2}$. The mechanism *exists* unconditionally at substrate level; the physical mass gap value is INHERITED via the kernel-profile-rescaling condition.

Mass-gap survival in the continuum limit is conditional on $c_{V1}(\ell_P)\ell_P^{-2} \to m_{\text{phys}}^2 > 0$ as $\ell_P \to 0$. ED supplies the structural mechanism; the rescaling exponent that determines whether the gap survives at finite positive value is value-INHERITED.

OS positivity is preserved channel-by-channel under the ED canonical content — kinetic (positive-definite for compact G), self-interaction (positive in Euclidean signature), matter source (non-negative bilinear), higher-derivative (non-negative via V1 positivity). Combined Euclidean action bounded below + reflection-positive at the structural-suggestive level.

The gauge-fixing obstruction is reframed via substrate gauge-quotient identification (T17 clause C8). Standard constructive YM has historically hit obstructions at OS-positivity preservation in the gauge-fixing sector — particularly via Gribov copies in non-perturbative gauge-fixing regimes. ED's substrate-level gauge-quotient identification reframes this from a continuum-gauge-fixing technical problem to a substrate-quotient-commutes-with-DCGT-coarse-graining structural question. The reframing is structurally significant; the rigorous resolution remains a separate technical question.

No constructive proof of YM existence or mass gap is claimed. The Clay Yang-Mills Existence and Mass Gap problem requires constructive proof of YM existence with mass gap on $\mathbb{R}^4$ at the level of Streater-Wightman / Osterwalder-Schrader axioms. The present analysis is structural — the ED account of YM existence and mass gap under substrate-discrete-and-finite assumptions, with OS-positivity preservation analyzed but not proven in full constructive rigor.

The arc identifies the load-bearing structural conditions for a positive Clay-relevance verdict:

1. **Compact gauge group** (INHERITED, value-layer).
2. **V1 positive Fourier transform** (FORCED, substrate-level).
3. **Kernel-profile rescaling condition** (INHERITED, value-layer).
4. **Matter-sector OS positivity** (structurally backed by closed work).

If all four hold, the canonical-ED sector of the ED-derived YM theory is structurally compatible with OS positivity and mass-gap survival. ED supplies (2) FORCED at substrate level and structural backing for (4); (1) and (3) are INHERITED at value layer.

Explicitly: this is not a solution to the Clay Millennium Problem. It is a structural analysis identifying the conditions under which the ED substrate $\to$ continuum mapping is compatible with the Clay axioms. The contribution is the substrate framing of the YM equation, the substrate origin of the mass-gap mechanism, the channel-by-channel OS-positivity audit, and the precise specification of the kernel-profile-rescaling condition as the load-bearing INHERITED condition.

This Clay-relevance framing is parallel in form and honesty to the main paper's Intermediate Path C verdict on Clay-NS: ED supplies a real structural mechanism; identifies the load-bearing condition; does not claim a Clay-problem solution.

E.7 Integration with Main Text

This appendix interacts with the main paper and the previous appendices in five specific ways:

(a) Complements Appendices C and D. Appendix C established the ED-I-06 ontological reading of NS / MHD content under the canonical-ED / non-ED boundary. Appendix D established the substrate-to-continuum bridge (DCGT) for the canonical-ED dynamical content of NS / MHD. Appendix E extends both to the non-Abelian gauge sector: the YM architectural classification (§E.4) follows the Appendix C template; the YM substrate-derivation (§E.2) follows the Appendix D template (DCGT methodology generalized to non-Abelian gauge fields). The three appendices together form a coherent architectural-and-substrate account of the canonical-ED dynamical sector across NS, MHD, and YM.

(b) Extends the NS Synthesis Paper into a unified NS / MHD / YM structural foundation. The paper, as of the addition of Appendix E, presents: - Architectural classification (main paper §3–§6 + Appendix C + §E.4). - Substrate-to-continuum derivation (Appendix D + §E.2). - ED-I-06 ontological reading (Appendix C + §E.4). - Mass-gap / smoothness / Clay-relevance verdicts (main paper Intermediate Path C for Clay-NS; §E.3 + §E.6 for Clay-YM). - OS-positivity audit (§E.5).

The paper now covers the full closed-arc landscape of the program's continuum-fluid-mechanics + non-Abelian-gauge work.

(c) Positions the ED program for the ED-QFT unified overview paper. The unified-overview publication will combine the closed structural-foundation work (T17 / T18 / Theorem N1 / Theorem GR1 / DCGT) with the applied-arc work (NS / MHD / YM / substrate-gravity) into a single program-overview publication. Appendix E supplies the YM building block of that unified picture, parallel to Appendices C and D supplying the NS / MHD building blocks. The NS Synthesis Paper, with all five appendices in place, becomes the canonical closed-arc reference for the continuum-fluid-mechanics + non-Abelian-gauge sector of the program.

(d) Preserves all main-paper headline disclaimers. The main paper's honest disclaimers — ED does not resolve whether 3D NS blows up at finite time, does not predict critical Reynolds numbers, does not supply a turbulence-cascade architectural template — remain unchanged. Appendix E adds parallel honest disclaimers for YM: ED does not solve the Clay YM-existence-and-mass-gap problem, does not predict numerical mass-gap values, does not derive the Standard Model gauge group, does not couple to spacetime curvature. What ED *does* deliver — for both fluid-mechanical and gauge sectors, under both structural and substrate readings — is a structurally coherent account of the canonical-ED dynamical content with explicit identification of the load-bearing conditions for Clay-relevance.

(e) Maintains the form-FORCED / value-INHERITED methodology across all sectors. Every canonical-ED content channel in §E.2 (substrate YM equation), §E.3 (mass-gap mechanism), §E.4 (architectural classification), and §E.5 (OS-positivity audit) is form-FORCED at substrate level with values INHERITED at value layer per the program's standard methodology. The structural verdicts are unconditional in form; the numerical content (specific gauge group, gauge coupling, mass-gap value, kernel-profile rescaling exponent) is INHERITED. This is the honest methodological framing that the main paper and the previous appendices have preserved, and Appendix E continues it.

Appendix E presents the Yang-Mills synthesis and Clay-relevance statement. Substrate-derived continuum YM equation $D_\mu F^{\mu\nu} = J^\nu$ via DCGT generalized to non-Abelian gauge fields + T17 generalized minimal coupling + non-Abelian rule-type bracket structure. Substrate mass-gap mechanism via V1 second-moment expansion + non-Abelian quartic stabilization, with

continuum-limit survival conditional on kernel-profile rescaling $c_{V1}(\ell_P)\ell_P^{-2} \to m_{\text{phys}}^2 > 0$. *Architectural classification: 4 canonical-ED / 2 non-ED, no transport-kinematic obstruction class — structurally cleaner than NS or MHD. OS-positivity audit channel-by-channel structural-suggestive positive conditional on 4-condition preservation locus (compact gauge group, V1 positive Fourier transform, kernel-profile rescaling, matter-sector positivity). Clay-relevance statement parallel in form and honesty to NS-Smoothness Intermediate Path C: ED supplies the structural mechanism + identifies load-bearing conditions; does not claim Clay-problem solution. The NS Synthesis Paper, with Appendices C + D + E in place, presents a unified architectural-and-substrate account of NS, MHD, and YM canonical-ED dynamical content. The program is now positioned for the ED-QFT unified overview paper as the next major publication move.*
