

Event Density and Galactic Curvature: A Speculative Alternative to Dark Matter

Allen Proxmire

December 2025

Abstract

This note explores a speculative alternative to dark matter: that some gravitational anomalies arise not from unseen mass, but from variations in the local structure of time. In general relativity, slower proper time corresponds to deeper gravitational potential. We propose that large-scale astrophysical systems generate temporal tension—a field-like quantity sourced by event density (interaction rates, turbulence, causal activity) and shaped by rotation and shear. This temporal tension diffuses outward from the dense galactic core, forming a smooth temporal halo that slows time in the outskirts. The resulting temporal gradient deepens the effective gravitational potential and can reproduce flat rotation curves and lensing signatures without invoking particulate dark matter. Because temporal halos are field configurations rather than collisionless matter, they should exhibit distinctive observational signatures, including halo lag in collisions, correlations with dynamical activity, smoother profiles, hysteresis, and possible vortex-like distortions. The aim here is not to present a full theory, but to articulate a simple, testable hypothesis: galaxies may be embedded in wells of time rather than clouds of matter.

1. Introduction

Galactic rotation curves, gravitational lensing, and cluster dynamics suggest a mismatch between visible matter and the gravitational potentials inferred from observation. The standard explanation is that galaxies reside in massive halos of non-luminous, collisionless dark matter. While successful on many scales, this framework faces persistent challenges, including the absence of direct detection and tensions in small-scale structure.

Galaxies are not silent structures; they churn, collide, radiate, and shear. They are places where the universe is busy with itself. This motivates a simple question: if galaxies are engines of dynamical activity, could they also be engines of temporal structure?

If the rate of time is sensitive not only to mass-energy but also to the density of events—interactions, turbulence, causal activity—then large-scale astrophysical systems may generate extended temporal structures that influence curvature. The goal of this note is to articulate this idea clearly enough to evaluate its plausibility and identify observational consequences. The proposal is conceptual rather than mathematical, intended as an invitation for further exploration.

2. Hypothesis

The central hypothesis is that event density and dynamical activity generate temporal tension, a field-like quantity that slows the local rate of proper time. This temporal tension diffuses outward from the dense galactic core, forming a smooth, extended temporal halo. Because slower time corresponds to deeper gravitational potential, the temporal halo contributes an additional potential term that dominates in the outskirts of galaxies, producing flat rotation curves and lensing signatures typically attributed to dark matter.

This hypothesis does not modify Newtonian dynamics or introduce new particles. It proposes that **temporal structure, shaped by causal activity, contributes to curvature alongside mass-energy**.

To explore this possibility, we outline a minimal conceptual model that captures the essential behavior of temporal tension without committing to a full mathematical formulation. Additionally, we offer several testable observational signals that would distinguish a temporal model from a dark matter one.

3. Conceptual Model

3.1 Event Density and Temporal Tension

Galaxies host intense dynamical activity: gravitational encounters, turbulence, magnetic reconnection, radiation exchange, star formation, and feedback processes. These interactions constitute a high event density—a large number of causal updates per unit volume.

The hypothesis posits that event density generates temporal tension, a thickening or slowing of proper time. This introduces a regulatory feedback: high event density increases temporal tension, which slows time, which in turn reduces the rate of further events. In this view, galaxies act as time sinks — regions where intense dynamical activity thickens the temporal fabric, drawing time into a slower state that deepens the effective gravitational potential.

3.2 Diffusion and Halo Formation

Temporal tension diffuses outward from the galactic core, smoothing local variations and forming a broad, extended temporal halo. Diffusion naturally produces:

- smooth radial profiles
- extended reach beyond the luminous disk
- approximate spherical symmetry

In the outskirts, where baryonic mass density falls rapidly, the temporal halo dominates the effective potential.

3.3 Temporal Drag and Vorticity

Galactic rotation and shear stir the temporal field, generating:

- temporal drag, analogous to frame dragging
- temporal vorticity, analogous to vortices in fluids

Rotation does not merely move matter — it stirs the temporal fabric, much as a whirlpool gathers the sea into ordered motion. The temporal field may form vortex-like structures that wrap around the galaxy, reminiscent of the ordered chaos described in Poe’s *A Descent into the Maelström*.

3.4 Dynamical Behavior of Temporal Halos

As field configurations, temporal halos exhibit:

- stability over orbital timescales
- memory (finite relaxation times)
- smoothness (reduced small-scale clumping)
- vortex-like behavior in interactions

If temporal halos behave as described, they should leave traces in the sky — patterns, lags, asymmetries, and smoothness that differ from those expected of collisionless matter.

4. Observational Signatures and Tests

The temporal-field interpretation yields several qualitative predictions that differ from standard dark matter:

1. Halo lag in collisions: temporal halos may shear or lag during cluster collisions.
2. Correlation with event density: halo strength should track dynamical activity, not mass alone.
3. Reduced small-scale substructure: diffusion suppresses clumping relative to CDM.
4. Hysteresis: halos respond slowly to recent mass redistribution.
5. Vortex-like distortions: interacting systems may show swirl-like lensing patterns.
6. Asymmetry: halos may reflect bars, warps, or asymmetric star formation.
7. Rotation dependence: fast-rotating galaxies may host stronger halos.
8. Temporal lensing deviations: subtle differences in shear profiles may appear.
9. Temperature independence: halo strength depends on current activity, not thermal history.

These signatures place the temporal-field hypothesis within a broader landscape of attempts to understand galactic dynamics. Many can be evaluated with existing data.

5. Relation to Existing Approaches

The temporal-field hypothesis sits between several established frameworks:

- CDM: preserves standard gravity but replaces unseen matter with temporal structure.
- MOND: differs by tying modifications to event density rather than acceleration.
- Emergent gravity: shares the idea of structural contributions to curvature but not the entropic mechanism.
- Scalar-field models: similar in introducing a field, but the temporal field is sourced by causal activity rather than mass-energy.

The distinctive feature is the claim that event density shapes temporal structure, which in turn shapes curvature.

6. Limitations and Open Questions

Of course, any speculative framework must acknowledge its boundaries. Key open questions include:

- the absence of a formal field equation
- how temporal tension fits into general relativity
- cosmological implications
- quantitative predictions for rotation curves and lensing
- the microphysical meaning of “event density”
- behavior in extreme environments
- whether temporal halos can be empirically distinguished from dark matter

These limitations define the work needed to evaluate the hypothesis.

7. Conclusion

Despite these open questions, the idea offers a conceptual lever worth articulating. This note proposes that galaxies may generate temporal tension through their internal dynamics, and that this tension diffuses into extended temporal halos that slow time and deepen the effective gravitational potential. This mechanism can reproduce key gravitational phenomena without invoking unseen matter and yields distinctive observational signatures. If time has texture, galaxies may be the places where that texture becomes visible.
